Electronic Structures and Optical Absorption Properties of Ni-doped Anatase TiO\textsubscript{2} for Photocatalysis from First-Principles Calculation

Maochang Liu, Zhaohui Zhou, Mingtao Li, Liejin Guo*, State Key Laboratory of Multiphase Flow in Power Engineering, School of Energy and Power Engineering, Xi'an Jiaotong University, 28, Xianning Street, Xi'an, Shaanxi 710049, China

From the viewpoint of photocatalysis, it is the anatase form of TiO\textsubscript{2} that is most important. Ti ions in the lattice were substituted by Ni ions to form Ni-doped TiO\textsubscript{2} which has been applied successfully for degradation of hazardous organic compounds or production of hydrogen or oxygen gas [1-4]. Therefore, a DFT calculation for the band structures and optical absorption spectra with varying Ni concentration in anatase TiO\textsubscript{2} models was conducted, in order to explore the effects of Ni doping on the band structure, photocatalytic property, and optical absorption spectrum.

The plane-wave pseudopotential method, implemented by CASTEP package [5], has been used to optimize crystal geometries, obtain the corresponding band structures and simulate the optical absorption spectra.

![Figure 1: The crystal structure of pure TiO\textsubscript{2} (Model a).](image)

2×1×1, 2×2×1, and 2×2×2 supercells with one Ti atom replaced by one Ni atom were denoted as Model (b), (c), and (d) to simulate doping concentration of 0.125, 0.062, and 0.031, respectively. Pure TiO\textsubscript{2} denoted as Model (a) was also calculated for comparison, as shown in Figure 1.

The optimized structural parameters of $a$, $c$ and $u \ (u = d_{ap}/c, \ d_{ap}$ is the apical Ti-O bond length) for pure anatase TiO\textsubscript{2} were listed in Table 1, which showed good consistence with

experimental [6] and theoretical results [7]. Six Ti-O bonds were contained in the distorted TiO₆ octahedron: \(d_{ap}=2.001\,\text{Å}\) and \(d_{eq}=1.941\,\text{Å}\), while \(d_{ap}=1.898\,\text{Å}\) and \(d_{eq}=1.919\,\text{Å}\) in NiO₆ octahedron for Model (c) and (d). The local symmetry \(D_{2d}\) for the NiO₆ octahedron was remained in Ni doped TiO₂ with low Ni concentration. Mulliken population analysis [8] showed that the charge on the Ni ion was about 0.88, independent of its concentrations in the crystal and smaller than the charge (1.33) on the original Ti ion in this site. The adjacent six oxygen ions at vertices of the NiO₆ octahedron were slightly reduced. The charges on them were -0.61 in Model (c) and (d), while the charges on oxygen ions of the TiO₆ octahedron were -0.66.

Band structure plots for pure (Model a) and doped (Model c) TiO₂ were shown in Figure 2. It was indicated from Figure 2a that pure TiO₂ was an indirect band gap semiconductor with a minimum band gap of 2.13eV. The top of valence bands was near M point and the bottom of conduction bands was at G point. The underestimated band gap (3.2eV for experimental value) was well known for DFT method. After Ni doping, two dopant bands which were marked with solid squares (Figure 2c) appeared in the band gap of TiO₂. These bands were unoccupied, so they would be acceptor levels upon visible light excitation.

![Figure 2: Band structure plots for pure (Model a) and doped (Model c) anatase TiO₂. The top of the valence band was denoted as zero.](image-url)
Partial density of states (PDOS) plots calculated for TiO$_2$ with different concentrations of Ni impurity were presented in Figure 3. For pure TiO$_2$ in Figure 3(a), the upper valence bands showed a strong hybridization between O 2p and Ti 3d orbitals. The top of the valence bands was dominated by the O 2p orbitals, while the conduction bands, especially the bottom, contained significant contributions from the Ti 3d orbitals. It was obvious from Model (b), (c) and (d) in Figure 3 that the doped Ni 3d orbitals substantially contributed to the valence bands and the impurity bands. Two narrow bands (band I and II as shown in Figure 3c) were located in the middle of the band gap for Model (c) and (d). As Wang et al. [9] clarified for V doped TiO$_2$, the D$_{2d}$ symmetry caused the three-fold degenerate t$_{2g}$ (3d$_{xy}$, 3d$_{xz}$, and 3d$_{yz}$) and two-fold degenerate e$_g$ (3d$_{x^2-y^2}$ and 3d$_{z^2}$) of a transition metal cation to further split; the t$_{2g}$ split into a two-fold degenerate level of both 3d$_{xz}$ and 3d$_{yz}$ and a level of 3d$_{xy}$ while the e$_g$ split into two levels of 3d$_{x^2-y^2}$ and 3d$_{z^2}$. Through a further examination of the orbital wavefunction contour maps of band I and II, the orbital contours for band I and band II showed the σ antibondings between O p$_x$ or p$_y$ orbital and Ni d$_{x^2-y^2}$ orbital and between O p$_z$ orbital and Ni d$_{z^2}$ orbital.

![Figure 3: Partial density of states plots for different concentrations of Ni impurity in anatase TiO$_2$. The unit for density of states is electrons/eV, x: doping concentration.](image)

In addition, Optical absorption spectra were calculated for different concentrations of Ni-doped anatase TiO$_2$ and the results were shown in Figure 5. The curve (a) for pure TiO$_2$ was calculated as a benchmark for comparing the results for Ni-doped TiO$_2$. For lower Ni impurity concentrations, curve (c) and (d) were very similar in the overall shape. The absorption for visible light with the characters of the shoulders around 450 nm and the tails reaching 700 nm was observed.
In summary, Ni doping had significant effect on electronic structure, optical absorption, and even photocatalytic property of anatase TiO$_2$. By introducing deep localized acceptor levels in the band gap, the response for visible light can be realized and the optical absorption spectra show the characters of the shoulder around 450 nm and the tail reaching 700 nm when Ni concentration approaches the experimental value. A schematic diagram of the band structure for Ni-doped anatase TiO$_2$ vs. normal hydrogen electrode (NHE) potential was drawn, as shown in Figure 5. This type of band structure was reasonable for the interpretation for various experimental phenomena.
