We report inelastic neutron-scattering measurements of crystal-field transitions in PrFeAsO, PrFeAsO$_{0.87}$F$_{0.13}$, and NdFeAsO$_{0.85}$F$_{0.15}$. Doping with fluorine produces additional crystal-field excitations, providing evidence that there are two distinct charge environments around the rare-earth ions, with probabilities that are consistent with a random distribution of dopants on the oxygen sites. The 4$f$ electrons of the Pr$^{3+}$ and Nd$^{3+}$ ions have nonmagnetic and magnetic ground states, respectively, indicating that the enhancement of $T_c$ compared to LaFeAsO$_{1-x}$F$_x$ is not due to rare-earth magnetism.

DOI: 10.1103/PhysRevB.83.212505 PACS number(s): 74.70.Xa, 74.62.Dh, 71.70.Ch, 78.70.Nx

Tuning materials to enhance their properties is the driving force behind much of modern condensed-matter physics. Chemical doping is often the most practical means of accomplishing this goal, but a thorough microscopic understanding of the effect of doping is a major challenge. For example, the role of phase separation in the high-temperature superconducting cuprates$^1$ and colossal magnetoresistive manganites$^2$ is still being debated. In the recently discovered iron-based superconductors, chemical doping is the primary method of inducing superconductivity, but there is conflicting evidence whether this is due to chemical pressure,$^3$ the change in carrier concentration,$^4$ disorder,$^5$ or a combination of all three. Moreover, the question of phase separation in the superconducting phase itself has not been conclusively answered and may be material dependent, with evidence of both phase separation into antiferromagnetic and superconducting regions$^6$ and phase coexistence.$^7$

The RFeAsO$_{1-x}$F$_x$ ($R =$ La, Ce, Pr, Nd, Sm, Gd) series$^8$–$^{15}$ was the first family of iron-based superconductors to be discovered. Replacement of lanthanum with other rare-earth elements increases $T_c$ up to $\sim 55$ K in the optimally doped regime close to $x = 0.15$. Doping with fluorine adds electrons into iron $d$ bands, but the substitution of trivalent rare-earth elements for lanthanum does not change the carrier concentration, so any changes are either due to the influence of local 4$f$ magnetism or the effect of chemical pressure from the well-known lanthanide contraction. Understanding which of these is responsible for the enhancement of $T_c$ has not been resolved. Recent neutron diffraction, muon spin relaxation ($\mu$SR), and Mössbauer studies of the RFeAsO parent compounds have shown evidence for strong coupling between rare-earth and iron magnetism.$^{16–19}$ Assuming that this coupling persists in fluorine-doped systems, we might expect the 4$f$ moments to influence the superconducting properties as well. Indeed, a recent$^{20}$ $^{19}$F NMR study of SmFeAsO$_{1-x}$F$_x$ has inferred a non-negligible coupling between the 4$f$ and conduction electrons.$^{20}$

Measurements of rare-earth crystal-field (CF) excitations using inelastic neutron scattering provide unique insight into the effects both of substituting magnetic rare-earth ions for lanthanum and of doping fluorine onto the oxygen sublattice. This is because it is both a local probe since the CF potential acting on the 4$f$ electrons is determined by the electrostatic environment produced predominantly by the nearest-neighbor oxygen or fluorine ions and a bulk probe since the CF transition intensities are a true thermodynamic average of the whole sample. Relative changes in the CF peak intensities can be directly related to the volume fraction of rare-earth ions affected by a particular configuration of neighboring ligands.

In this article, we present a comparison of CF excitations measured in PrFeAsO$_{1-x}$F$_x$ with $x = 0.0$ and 0.13, which shows that there are two distinct charge environments in the superconducting compound, similar to the conclusions of a recent$^{21}$ $^{75}$As nuclear quadrupole resonance (NQR) study. However, the measured reduction in CF intensity with $x$ is consistent with a random distribution of fluorine ions, showing that the charge environments are produced by the dopant ions and not electronic phase separation in the iron layers, as proposed in the earlier work. Similarly, our measurements on NdFeAsO$_{0.85}$F$_{0.15}$ reveal more crystal-field excitations than would be allowed due to either tetragonal or orthorhombic symmetry, also indicating the presence of inequivalent rare-earth sites. Moreover, we are able to eliminate or severely constrain the relevance of rare-earth magnetism to the pairing mechanism since superconducting PrFeAsO$_{0.87}$F$_{0.13}$ has a singlet ground state while superconducting NdFeAsO$_{0.85}$F$_{0.15}$ has a magnetic Kramer’s doublet ground state, even though both the superconducting transition temperatures are similar.$^{9,10}$

Powder samples of RFeAsO$_{1-x}$F$_x$ were synthesized following the method described in Ref. 19. Superconducting transition temperatures determined by the onset of diamagnetism in an applied field of 20 Oe are 41 and 49 K for PrFeAsO$_{1-x}$F$_x$ ($x = 0.13 \pm 0.01$ determined from the phase diagram of Ref. 22) and NdFeAsO$_{0.15}$ (nominal composition), respectively. Structural characterization by neutron diffraction was
performed on GEM at the ISIS Facility and HB2A at the High Flux Isotope Reactor. Inelastic neutron-scattering (INS) studies were conducted on time-of-flight spectrometers Merlin at ISIS and IN4 and IN6 at the Institut Laue-Langevin. The INS data have been placed on an absolute scale by normalization to a vanadium standard.

Figure 1 shows the neutron-diffraction pattern for PrFeAsO$_{0.87}$F$_{0.13}$ measured at 4 K, compared to a Rietveld fit using FULLPROF. Structural refinements confirmed the orthorhombic ($Cnma$) structure in the parent compound and the tetragonal ($P4/nmm$) structure in the superconducting sample, with evidence for 4.3% $\pm$ 0.2% of FeAs impurity in both the $x = 0.0$ and 0.13 compounds. A PrOF impurity phase ($\sim 3.8\%$) is also detectable in PrFeAsO$_{0.87}$F$_{0.13}$, but it is too small to produce the CF excitations discussed below. There is no evidence of structural inhomogeneity in the primary phases of PrFeAsO and PrFeAsO$_{0.87}$F$_{0.13}$. No impurity phase was observed in NdFeAsO$_{0.87}$F$_{0.15}$.

Figure 2 shows the CF excitations in PrFeAsO and PrFeAsO$_{0.87}$F$_{0.13}$ below 14 meV. The crystal-field excitations are evident as the peaks at nonzero energy transfers that are not present in LaFeAsO, which has no $4f$ electrons. There are additional CF excitations between 30 and 40 meV, which are not shown. In the parent compound, PrFeAsO, the CF excitations centered at $\sim 3.5$ meV are split above $T_N(\text{Pr}) = 12$ K. We assume that this is due to the internal molecular field created by the Fe sublattice below $T_N(\text{Fe}) = 127$ K, although we cannot confirm that they become degenerate above $T_N(\text{Fe})$ because of thermal broadening. We have insufficient information to solve the CF potential, so we cannot construct a microscopic model to explain the collapse of the splitting when the rare-earth sublattice magnetically orders as seen in the inset of Fig. 2(a). However, it may be due to a spin reorientation, similar to what has been observed in NdFeAsO, and is consistent with other evidence of an interplay between iron and rare-earth magnetism in PrFeAsO, such as a reduction in the intensity of the iron magnetic Bragg peak and a reduction in the $\mu$SR frequency approaching $T_N(\text{Pr})$.

In PrFeAsO$_{0.87}$F$_{0.13}$, there is also a CF peak at $\sim 3$ meV (labeled A in Fig. 2(b)), but there is no evidence of any splitting, which is consistent with the absence of long-range magnetic order of the iron sublattice. However, the most striking observation is the appearance of two extra CF peaks at 9.72 $\pm$ 0.05 and 11.8 $\pm$ 0.1 meV (labeled B and C, respectively) in the superconducting compound. There are no structural or magnetic phase transitions, and the amount of PrOF impurity phase is far too small to explain them. The temperature dependence of their intensities confirms that all the transitions represent transitions from the ground state. However, the intensity of peak A decreases much faster than the intensities of peaks B and C. As can be seen in Fig. 2(b), between 1.5 and 50 K, the intensity of peak A falls by a factor...
dependence of the intensity of peak C is similar to peak B. The transitions at
derived from the inelastic neutron-scattering data for the crystal-field
and 1
Gaussian line shape. The superconducting compounds are quite small and have a
substantial clustering of fluorine ions on the oxygen sublattice. The value is sufficiently precise to be strong evidence against any.

The widths of the CF transitions in both the parent and superconducting compounds are quite small and have a Gaussian line shape. The ~3 meV peak width (full width at half maximum) at 1.5 K is 0.61 ± 0.02 meV in PrFeAsO and 1.54 ± 0.03 meV in PrFeAsO0.85F0.15, after correction for the instrumental resolution. This indicates that there is some broadening from chemical disorder, probably produced by lattice strains due to longer-range fluctuations in the configuration of fluorine neighbors. The fact that we are seeing well-defined, sharp CF transitions in the superconducting compound is evidence that the distribution of structural or electronic defects around the praseodymium ions is small and that we are dealing with two well-defined charge environments.

Another example where fluorine doping produces multiple rare-earth environments in an RFeAsO1−xFx material is for R = Nd. The INS data for NdFeAsO0.85F0.15 measured on the Merlin spectrometer at 7 and 50 K and at initial energies 15 and 30 meV are shown in Fig. 4(a). For Nd3+ ions in a point-group symmetry lower than cubic, i.e., tetragonal, orthorhombic, or monoclinic, the J = 9/2 ground-state multiplet breaks up into five Kramers doublets, so there can be at most four CF transitions from the ground state. There are clearly five peaks due to ground-state CF transitions, and thus, while it is difficult to assign each peak to a particular rare-earth site, the data are consistent with the picture presented above, in which the local electrostatic potential of the rare-earth ion is modified by fluorine doping.

These observations bear some similarity to recent NQR measurements showing the existence of two charge environments in underdoped RFeAsO1−xFx for R = La and...
Sm. The $^{75}$As NQR is sensitive to the electric-field gradient, i.e., the second-degree CF potential, acting on the arsenic sites, which is also affected by changes in the local fluorine ion distribution. However, Lang et al. argue that the two spectral components they observe in the superconducting phase are due to local electronic order on the iron layer because of the dependence of the spectral weights. It is more difficult to model the effect of different fluorine ion configurations because of the greater distance of the arsenic ions from the oxygen-fluorine sublattice and the longer range of the second-degree CF potential, at least in ionic environments. It is clear that their data are more affected by inhomogeneous broadening than the neutron data, making the spectral weight ratios more difficult to determine, so we cannot rule out their interpretation, but it seems unlikely that two such similar probes should both find evidence of two charge environments with completely different origins.

The final issue we wish to comment on is the effect that rare-earth substitution has on superconductivity. As stated earlier, the rare-earth substituents are isovalent to lanthanum means that the increase in $T_c$ is either due to chemical pressure from their smaller ionic size or due to the $4f$ magnetic moments coupling to the iron magnetism and influencing the pairing interaction. The high-resolution neutron-scattering data shown in Figs. 4(b)–4(e) show that the low-energy magnetic fluctuations are very different in PrFeAsO$_{1−x}$F$_x$ and NdFeAsO$_{1−x}$F$_x$ compounds that are due to a random distribution of fluorine ions, rather than electronic phase separation on the iron layers, as proposed in an earlier NQR study. Measurements of low-energy magnetic fluctuations reveal that Pr$^{3+}$ and Nd$^{3+}$ $4f$ electrons have nonmagnetic and magnetic CF ground states, respectively, from which we infer that the $4f$ magnetic moments are not responsible for the nearly identical enhancement of superconductivity in these compounds compared to LaFeAsO$_{1−x}$F$_x$ and conclude that a more likely candidate is chemical pressure produced by the lanthanide contraction.

We acknowledge useful discussions with E. Dagotto and assistance in the neutron-scattering experiments from O. Garlea (ORNL), T. Guidi (ISIS), A. Orecchini (ILL), and M. Koza (ILL). Research at Argonne and Oak Ridge is supported by the US Department of Energy, Office of Science, Office of Basic Energy Sciences, Materials Sciences and Engineering Division and Scientific User Facilities Division (Argonne Contract No. DE-AC02-06CH11357).
