Employing first-principles electronic-structure calculations in conjunction with the frozen-magnon method, we calculate exchange interactions, spin-wave dispersion, and spin-wave stiffness constants in inverse-Heusler-based spin gapless semiconductor (SGS) compounds Mn₂CoAl, Ti₂MnAl, Cr₂ZnSi, Ti₃CoSi, and Ti₃VAs. We find that their magnetic behavior is similar to the half-metallic ferromagnetic full-Heusler alloys, i.e., the intersublattice exchange interactions play an essential role in the formation of the magnetic ground state and in determining the Curie temperature $T_c$. All compounds, except Ti₂CoSi, possess a ferrimagnetic ground state. Due to the finite energy gap in one spin channel, the exchange interactions decay sharply with the distance, and hence magnetism of these SGSs can be described considering only nearest- and next-nearest-neighbor exchange interactions. The calculated spin-wave dispersion curves are typical for ferrimagnets and ferromagnets. The spin-wave stiffness constants turn out to be larger than those of the elementary 3d ferromagnets. Calculated exchange parameters are used as input to determine the temperature dependence of the magnetization and $T_c$ of the SGSs. We find that the $T_c$ of all compounds is much above the room temperature. The calculated magnetization curve for Mn₂CoAl as well as the Curie temperature are in very good agreement with available experimental data. This study is expected to pave the way for a deeper understanding of the magnetic properties of the inverse-Heusler-based SGSs and enhance the interest in these materials for application in spintronic and magnetoelectronic devices.

I. INTRODUCTION

Heusler compounds and alloys are a huge family of intermetallic compounds [1,2] and they owe their name to the German metallurgist Friedrich Heusler who in 1904 studied the thermodynamic properties of Cu₂MnAl [3]. The development of the research fields of magnetoelectronics and spintronics [4] intensified the interest in the half-metallic Heusler compounds [5–7]. In half-metallic magnets, a metallic majority-spin electronic band structure and a semiconducting minority-spin electronic band structure coexist [8,9]. Such compounds could lead to the creation of a fully spin-polarized current, maximizing the efficiency of spintronic devices [10]. In addition, half-metallicity in Heusler compounds is always accompanied by the so-called Slater-Pauling rule where the total spin magnetic moment scales linearly with the number of valence electrons in the unit cell [11–16]. Although a large number of half-metallic Heusler compounds have been studied, still novel properties are discovered among Heusler alloys, e.g., ferromagnetic or ferrimagnetic semiconducting behavior [17–20], paving the way for diverse applications in spintronics/magnetoelectronics [21].

A class of materials bridging the gap between half-metals and magnetic semiconductors are the so-called spin gapless semiconductors (SGS), magnetic semiconductors where there is an almost zero-width energy gap at the Fermi level in the majority-spin direction and a usual energy gap in the other spin direction [22]. In SGS, (i) the mobility of carriers is considerably larger than in usual semiconductors, (ii) excited carriers include both electrons and holes which can be 100% spin polarized simultaneously, and (iii) a vanishing amount of energy is enough to excite majority-spin electrons from the valence to the conduction band. Several compounds have been identified as SGS [23–31], and among them exist a few Heusler compounds [16,32–35] and it is Mn₂CoAl, an inverse full-Heusler compound, which has attracted most of the attention due to its successful growth in the form of films. First, in 2008 Liu and collaborators synthesized using an arc-melting technique Mn₂CoAl and found that it adopted the lattice structure of inverse full Heuslers (see Fig. 1 for a schematic representation of the structure) with a lattice constant of 5.8388 Å and a total spin magnetic moment of 1.95 $\mu_B$ per formula unit [36]. The lattice of inverse Heuslers is known as the $XA \,(or \,X_{\alpha})$ structure and it is similar to the well-known $L_2_1$ structure of full Heusler compounds such as Co₂MnAl where only the sequence of the atoms in the unit cell changes. Moreover, electronic-structure calculations yielded a ferrimagnetic state with a total spin magnetic moment of 2.0 $\mu_B$ per formula unit and an antiparallel coupling between the Mn nearest-neighboring atoms [36]. Although the calculated structure in Ref. [36] is that of a SGS, authors do not mention it in their paper [36]. In 2011, Meinert and collaborators studied again theoretically this compound and almost reproduced the calculated results of Liu et al. using a different electronic-structure method [37]. They have also calculated the exchange constants showing that they are short range and the magnetic state is stabilized mainly due to the direct interaction between nearest neighbors and predicted a Curie temperature.
We present calculations of exchange interactions, spin waves, and temperature dependence of the magnetization in five inverse Heusler compounds known to present spin gapless semiconducting behavior studied in Ref. [32]: Mn$_2$CoAl, Ti$_2$CoSi, Ti$_2$MnAl, Ti$_2$VaS, and Cr$_2$ZnSi. We find that magnetic behavior of the SGSs is similar to the half-metallic ferromagnetic full-Heusler alloys, i.e., the intersublattice exchange interactions play an essential role in the formation of the magnetic ground state and in determining the critical temperature $T_C$. Note that even in the case of zero total spin magnetic moment in the unit cell, the compounds under study are fully compensated ferrimagnets and not conventional antiferromagnets, and thus the critical temperature should be called “Curie temperature” and not “Néel temperature.” It turns out that the $T_C$ of all compounds is much above the room temperature. The calculated magnetization curve for Mn$_2$CoAl as well as the Curie temperature are in very good agreement with available experimental data. The rest of the paper is organized as follows: In Sec. II, we present the computational method. In Sec. III, we present the computational results, and Sec. III gives the conclusions.

of 890 K [37]. But, it was not until 2013 when Ouardi et al. identified the SGS behavior of Mn$_2$CoAl and have confirmed it experimentally in bulklike polycrystalline films [38]. The experimental lattice constant was found to be 5.798 Å, the Curie temperature was measured to be about 720 K, and the total spin magnetic moment per formula unit was found 2 $\mu_B$ at a temperature of 5 K [38]. Following this research work, Jamer and collaborators have grown thin films of 70-nm thickness on top of GaAs [39], but these films were found to deviate from the SGS behavior [40]. On the contrary, films, grown on top of a thermally oxidized Si substrate, were found to be SGS with a Curie temperature of 530 K [41]. First-principles calculations of Skafthourou et al. identified among the inverse Heusler compounds four additional potential SGS materials: Ti$_2$CoSi, Ti$_2$MnAl, Ti$_2$VaS, and Cr$_2$ZnSi, the latter three being also fully compensated ferrimagnets, and V$_2$Al for which one V sublattice is not magnetic and the other two form a conventional antiferromagnet [32]. The SGS character of Ti$_2$MnAl was also confirmed by Jia et al. [42]. Wollman et al. [43] confirmed the conclusion of Meinert et al. that direct exchange interactions are responsible for the magnetic order in Mn$_2$CoAl studying a wide range of Mn$_2$-based Heusler compounds and predicted a Curie temperature of 740 K using the spherical approximation [44]. Skafthourou et al. have discussed in detail the behavior of the total magnetic moment in inverse Heusler compounds including the SGS materials [14]. Galanakis and collaborators have shown that defects keep the half-metallic character of Mn$_2$CoAl but destroy the SGS character [45]. Finally, recent studies on the effect of doping of Mn$_2$CoAl with Cu, Co, V, and Ti [46] as well as the anomalous Hall effect have appeared in literature [47].

Motivated by these recent advances in SGS systems, this work aims at a prediction and understanding of their magnetic properties at elevated temperatures. We employ density-functional theory at the ground state augmented by a Heisenberg model Hamiltonian for the prediction of the temperature-dependent magnetization.
approximation (GGA) exchange-correlation potential [50]. For Mn$_2$CoAl, the calculated value of 5.73 Å is slightly smaller than the experimentally determined lattice constants of 5.8388 and 5.798 Å in Refs. [36,38], respectively. We compute the ground-state electronic properties using the full-potential linearized augmented plane wave (FLAPW) method as implemented in the FLEUR code [51] combined with the GGA to the exchange-correlation potential as parametrized by Perdew et al. [50].

B. Exchange constants and spin-wave dispersion

Next, we present the formalism on which the calculations of the exchange constants are based. Our starting point is the classical Heisenberg model with unit vectors $\mathbf{e}_{na}$ pointing along the spin moments at positions $\mathbf{R}_{na}$ specified by a cell index $n$ and magnetic lattice index $a$. The spin moments interact via exchange coupling parameters $J_{mnαβ}^{αβ}$ and the exchange Hamiltonian $H_{ex}$ is

$$H_{ex} = -\frac{1}{2} \sum_{mnαβ} J_{mnαβ}^{αβ} \mathbf{e}_{na} \cdot \mathbf{e}_{nβ}. \quad (1)$$

Note that the magnitude of the moments is incorporated in the parameters $J$. The exchange parameters are extracted by a least-square fit from ab initio total-energy calculations performed using the FLEUR code for a set of spin spirals with randomized wave vectors [51,52]. To reduce the computational cost, we do non-self-consistent calculations and apply the approximation based on the magnetic force theorem [53,54] to obtain the total-energy differences from the differences in sums of eigenvalues.

In order to obtain the adiabatic magnon dispersion [52,55–57], we set up the spin-wave dynamical matrix $\Delta(\mathbf{q})$ at a Brillouin zone point $\mathbf{q}$ and solve for eigenvalues which provide the magnon frequencies:

$$\Delta^{αβ}(\mathbf{q}) = 2 \left( \delta^{αβ} \sum_γ J^{αγ}(\mathbf{q}) M_γ |M_γ| |M_α| - J^{αβ}(\mathbf{q}) |M_β| |M_α| \right), \quad (2)$$

$$J^{αβ}(\mathbf{q}) = \sum_n J^{αβ}_{0n} \cos[\mathbf{q} \cdot (\mathbf{R}_{na} - \mathbf{R}_{nβ})]. \quad (3)$$

Here, $M_α$ is the integrated magnetic moment of sub-lattice $α$. In order to obtain the spin stiffness $D$ of the compounds we fit a linear or quadratic form $D_0 |\mathbf{q}|$ or $D_0 |\mathbf{q}|^2$, respectively, to the adiabatic magnon energies along a high-symmetry line in the neighborhood of the Γ point (in cubic systems, $D$ is isotropic). A linear behavior is present for the conventional antiferromagnets and we find it here for the compensated ferrimagnets. We should also note that within our formalism, where we consider an adiabatic approach for the magnons, we cannot study the Landau damping of the spin waves induced by electron-hole excitations. In the compounds under study we expect the adiabatic approximation to provide reasonable results since there is a Stoner gap separating the magnon spectra from the continuum Stoner excitation spectra as in most half-metallic magnets (with the exception when the Fermi level is exactly at the higher-energy edge of the minority-spin energy gap).

C. Temperature dependence of the magnetization and $T_c$

We employ the classical Monte Carlo technique to calculate the temperature dependence of the magnetization that is derived from the Heisenberg exchange Hamiltonian (1). The technique provides an excellent estimation of the critical temperature $T_c^{MC}$ from the position of the peak of the susceptibility as a function of temperature calculated as $\chi(T) = [(M^2(T) - \langle M(T) \rangle)^2]/k_B T$, where $\langle \ldots \rangle$ denotes thermal averaging over Monte Carlo steps, $M(T)$ is the magnetization (before averaging), and $k_B$ is the Boltzmann constant. Use of a correction for finite-size effects, e.g., the fourth-order cumulant method [58], can give a more accurate estimation of the critical temperature, but the correction here is small (of the order of a few K) since we are using large simulation supercells ($12 \times 12 \times 12$ primitive cells corresponding to 5184 magnetic atoms). We employ the Metropolis algorithm [48] and as a random number generator we use the Mersene Twister [59]. The input comprises both the intersublattice and intrasublattice exchange constants considering only the magnetic atoms, neglecting any contribution due to the interaction of the low-moment $sp$ atoms. Moreover we ignore the contribution of the interstitial region [60].

From the exchange constants, the Curie critical temperature $T_c$ can be also estimated within the mean-field approximation (MFA). Actually, the critical temperature is given by the average value of the magnon energies which in MFA is the arithmetic average taking all the magnon values with equal weight, thus is an arithmetic property that the MFA estimation is larger than experimental values [61–63]. The MFA expression of the critical temperature for a multisublattice material such as Heusler compounds has been provided in literature [64,65].

III. RESULTS AND DISCUSSION

This section is divided into three parts. In the first part, we discuss the ground-state properties and magnetic moments of the studied compounds. The second part deals with the exchange interactions, spin-wave dispersions, as well as spin stiffness constants. The last part focuses on the temperature dependence of the magnetization and critical temperature. Note that Ti$_2$CoSi presents similar behavior to Mn$_2$CoAl and Ti$_2$VAs presents similar properties to Ti$_2$MnAl. Thus, we will focus our discussion mainly on Mn$_2$CoAl, Ti$_2$MnAl, and Cr$_2$ZnSi compounds.

A. Spin gapless semiconducting behavior and magnetic moments

The first step in the study of these materials is to establish their ground-state properties at 0 K as obtained from our first-principles calculations. In Fig. 2, we have plotted the density of states (DOS) projected on the transition-metal atoms for Mn$_2$CoAl, Ti$_2$MnAl, and Cr$_2$ZnSi and in Table I we present the atomic and total spin magnetic moments for all five compounds. We do not present band-structure plots since they are known from previous works [32,36]. In all studied compounds, we get a finite gap in the minority-spin band structure (negative values of DOS) and a zero-width gap in the majority-spin band structure. In the case of Mn$_2$CoAl
and Cr₂ZnSi, the Fermi level is located at the middle of the minority-spin energy gap and for Ti₂MnAl the Fermi level is located at the left edge of the gap. The position of the Fermi level within the gap is important with respect to the coupling between collective and single-electron excitations discussed later. For all five compounds under study, the total DOS per formula unit (f.u.) is similar to the ones calculated in Ref. [32] with a different full-potential method and thus spin gapless semiconducting behavior of these compounds is a robust prediction of \textit{ab initio} electronic-structure calculations.

Among the five studied compounds, Mn₂CoAl is a ferrimagnet and Ti₂CoSi a ferromagnet with total spin magnetic moments per f.u. of 2 and 3 $\mu_B$, respectively, and the other three compounds combine the SGS character to a fully compensated ferrimagnetic state presenting zero total spin magnetic moments per f.u. as shown in Table I. In the case of the four ferrimagnetic compounds, the $X$ atoms at the B sites couple: either (a) antiferromagnetically to the $X$ atoms at the A sites and ferromagnetically to the $Y$ atoms at the C sites (cases of Mn₂CoAl and Cr₂ZnSi), or (b) ferromagnetically to the $X$ atoms at the A sites and antiferromagnetically to the $Y$ atoms at the C sites (cases of Ti₂MnAl and Ti₂VAs). This behavior is expected from the so-called Bethe-Slater curve [66]. The early transition-metal atoms such as Cr and Mn, when they are close to each other in space, tend to have antiparallel spin magnetic moments. On the other hand, for the nearest Ti atoms, the coupling tends to be ferromagnetic (Tiₐ and TiₐB in Ti₂YZ compounds). This behavior is also reflected on the exchange constants calculated and presented in the next subsection. Interestingly, even in the case of Cr₂ZnSi, where Zn is almost nonmagnetic since all its $d$ states are occupied lying below the energy window presented in Fig. 2, the small induced spin magnetic moment at the Zn and Si atoms leads to a small imbalance of the spin moments between the two Cr atoms (Crₐ has as a spin moment of $-1.59 \mu_B$ and CrₐB of 1.64 $\mu_B$) and Crₐ resolved DOS presented in Fig. 2 is not an exact mirror image of the CrₐB DOS as in conventional antiferromagnets.

Finally, we should shortly discuss the values of the atomic spin magnetic moments presented in Table I. For all five compounds, spin moments are similar to the results in Ref. [32] where the FPLO [49] electronic-structure code has been employed. Moreover, for Mn₂CoAl results agree with the calculated values in Refs. [36–38] and for Ti₂MnAl with the results presented in Ref. [42]. Since in each study a different full-potential \textit{ab initio} method has been used, we can be confident of the validity of our results. Concerning now the experimentally available data, in Refs. [36,38] only the total spin magnetic moment per f.u. for Mn₂CoAl films on Si substrates has been measured which has been found to be 1.95 and exactly 2 $\mu_B$, respectively, in agreement with our calculated value of 2 $\mu_B$. A similar total spin magnetic moment (1.94 $\mu_B$) has been measured by Xu and collaborators [41] for Mn₂CoAl films on GaAs(001), where x-ray magnetic circular dichroism (XMCD) experiments where carried out. Although XMCD is a powerful technique, in Mn₂CoAl there exist two Mn atoms with opposite

FIG. 2. (Color online) Density of states (DOS) projected on the transition-metal atoms. In the case of Mn₂CoAl, positive (negative) DOS values correspond to the majority- (minority-) spin electrons. In the case of the other two compounds, which are fully compensated ferrimagnets, spin-up (positive DOS) and spin-down (negative DOS) electrons have been chosen such that the atomic spin magnetic moments in Table I have the right sign. Fermi level is set to the zero-energy value.
spin magnetic moments. XMCD can distinguish between different elements but cannot distinguish atoms of the same chemical element with different spin magnetic moments and thus the values of the Mn moments in Ref. [40] cannot be interpreted as atomic moments. Note that in the FLAPW method, the atomic spin magnetic moments are calculated by integrating the spin-dependent charge density within each muffin-tin sphere surrounding each atom. The interstitial region is not assigned to any atom. Although we have used almost touching muffin-tin spheres, we can see in Table I that in the case of Ti2MnAl and Ti2CoSi, a significant part of the spin magnetic moment is located at the interstitial region. This should be attributed to the fact that early transition metals have d states extending further away from the nucleus compared to late transition metals and the smaller the valence the more extended are the d states.

B. Exchange interactions and spin-wave dispersion

Our calculations have shown that in the compounds under study, intersublattice exchange interactions play a dominant role in formation of the magnetic state and critical temperature. In Fig. 3, we present the intersublattice exchange constants as a function of distance. Negative values of the exchange constants reflect an antiferromagnetic coupling of the corresponding spin moments and positive values a ferromagnetic coupling. In all compounds, the intersublattice nearest-neighbor interactions dominate and especially the interaction between the X atom and its Y nearest neighbors (Fig. 1). The interactions between next-nearest neighbors X and Y are expectedly weaker. In the case of Cr2ZnSi, the Zn atom is almost nonmagnetic while in the case of Mn2CoAl the intersublattice exchange constants between the MnA-MnA atoms have a sizable value despite their large distance. In the case of Ti2MnAl, the TiAB have positive spin moments and the Mn2 has negative spin moment as shown in Table I. The situation is different to Mn2CoAl where Mn3 site has negative, and MnB site and CoC have positive moments. Thus, the XA-XB and XB-Y interactions have different signs for the two compounds. We can conclude that for the SGs under study the interactions are short range: as seen from the Fig. 3 they decay quickly with the distance. This can be attributed to the existence of the finite spin gap as discussed in literature in detail for half-metallic Heusler compounds [62,67].

The short-range nature of exchange interaction in Mn2CoAl and similar compounds has been shown by Meinert and collaborators in Ref. [37]. Moreover, in the case of Mn2CoAl our results agree very well with the results obtained in Ref. [37], considering the difference of a prefactor 1⁄2 in the definitions of the Heisenberg Hamiltonian between Ref. [37] and this work. (Also note that in their notations the sequence of the atoms is Co-MnB-MnC-Al and thus our MnA atom corresponds to the MnA atom in their paper). Further calculations by Wollmann and collaborators on a series of Mn2-based inverse Heusler compounds have confirmed the short-range nature of the interactions in these materials [43].

TABLE II. Onsite intersublattice (e.g., \( J^{X_A-X_B}_0 = \sum_R J^{X_A-X_B}_0 \), where \( R \) is the lattice vector) and intersublattice (e.g., \( J^{X_A-X_B} = \sum_R J^{X_A-X_B}_0 \)) exchange constants (in meV), spin-wave stiffness constant \( D \) (in meV Å for compensated ferrimagnets or meV Å\(^2\) for ferrimagnets and ferromagnets), and the mean-field and Monte Carlo calculated critical temperatures (in K) for the compounds under study. Note that for the inverse \( XY \) compounds the two \( X \) transition-metal atoms occupy the A and B sites and the third transition-metal atom \( Y \) occupies the C site.

</table>
The contribution of each type of exchange interaction to the total exchange field \( J_0 \) (the Weiss field acting on a spin moment) is given by the sum of the interactions over all possible pairs or, partially, over all pairs within a sublattice. The calculated values for the intrasublattice and intersublattice \( J_0 \) are presented in Table II. Our results confirm the conclusions drawn in the previous paragraph. The onsite intersublattice \( J_0 \) are considerably larger than the intrasublattice \( J_0 \) and only in the case of \( \text{Mn}_2\text{CoAl} \) and \( \text{Ti}_2\text{VA}s \) the \( J_0^{\text{Mn-Mn}} \) and \( J_0^{\text{VA-VA}} \) makes a considerable contribution into the total exchange field with different signs.

In Fig. 4, we present the spin-wave dispersion along the high-symmetry lines in the Brillouin zone for \( \text{Mn}_2\text{CoAl}, \text{Ti}_2\text{MnAl}, \) and \( \text{Cr}_2\text{ZnSi}. \) Each spectrum has distinct features. First, the number of branches coincides with the number of magnetic atoms in the unit cell and thus we have three branches for \( \text{Mn}_2\text{CoAl} \) and \( \text{Ti}_2\text{MnAl} \) and two branches for \( \text{Cr}_2\text{ZnSi} \) where the Zn atom is not magnetic. The energy dispersion curves of all compounds under study are typical for magnets with short-range interactions, where nearest-neighbor and next-nearest-neighbor interactions dominate, and do not yield any instabilities. Instabilities can occur if the acoustic magnon modes have very low energies (close to zero) in some parts of the Brillouin zone but this is not the case for any of the studied compounds.

In the case of \( \text{Mn}_2\text{CoAl}, \) the acoustic branch shows a typical behavior of ferromagnets/ferrimagnets and around the \( \Gamma \) point the energy-dispersion curve shows a quadratic behavior with a spin-wave stiffness constant \( D \) of 677 meV Å\(^2\). This value exceeds typical values of transition-metal ferromagnets which usually range between 300 and 600 meV Å\(^2\) [62], and is close to the maximum known values of 715 meV Å\(^2\) for \( \text{Co}_2\text{FeSi} \) [68] and 800 meV Å\(^2\) for \( \text{Fe}_{53}\text{Co}_{47} \) [69]. \( \text{Ti}_2\text{CoSi} \) as shown in Table II exhibits a \( D \) value of 636 meV Å\(^2\) close to the value for \( \text{Mn}_2\text{CoAl}. \)

Although \( \text{Cr}_2\text{ZnSi} \) is not a true antiferromagnet, around the \( \Gamma \) point the energy dispersion is linear and the optical and acoustic branches coincide showing considerable difference only at the plateau close to the Brillouin zone boundary (\( X, W, L, K \) points in Fig. 4). The spin-wave stiffness constant as shown in Table II takes a value of 752 meV Å. In the case of \( \text{Ti}_2\text{MnAl}, \) the situation is more complicated. Due to the small spin moments of the Ti atoms around the \( \Gamma \) point, the energy dispersion of the acoustic magnon is practically linear but with a small value of the \( D \) constant (274 meV Å). \( \text{Ti}_2\text{VA}s \) also shows a behavior similar to \( \text{Ti}_2\text{MnAl} \) but now \( D \) has a much higher value of 598 meV Å.

C. Temperature dependence of magnetization and \( T_C \)

In this section, we show the temperature dependence of the magnetization and susceptibility calculated with the classical Monte Carlo technique. In Fig. 5, we present for \( \text{Mn}_2\text{CoAl}, \text{Ti}_2\text{MnAl}, \) and \( \text{Cr}_2\text{ZnSi} \) the temperature dependence of the sublattice and total magnetization per f.u. First, we compare our results to experiment. We plot for \( \text{Mn}_2\text{CoAl} \) our theoretical results together with the experimental results from the Ref. [38] where the temperature dependence of the total magnetization in a polycrystalline film was measured in a field of 1 T. The agreement between the two data sets is good with one curve falling on top of the other with the exception of the region close to the critical temperature. Our curve shows an abrupt decrease close to our calculated critical temperature of 770 K, while in experiments this sharp decrease is shifted lower in temperature since the measured critical temperature in Ref. [38] is 720 K, slightly smaller than our value. Thus, the Monte Carlo technique, which we employ, accurately
describes the temperature dependence of the magnetization, indicating also the accurate determination of the exchange constants.

In the case of Cr$_2$ZnSi, the picture is that of an antiferromagnet with a total spin magnetic moment being almost equal to zero for all temperatures since we have ignored the magnetic properties of the Zn atom. In the case of Ti$_2$MnAl, the calculated total magnetization (Fig. 5) is not exactly zero as expected from the first-principles result at 0 K (Table I) but it equals to $-0.46 \mu_B$ due to the spin moment of the Al atom and of the interstitial region which we have ignored in our Monte Carlo calculations. At and close to room temperature (up to $\approx 400$ K), where most devices operate, we find that all three compounds still have sizable values of the sublattice magnetization. Thus, the magnetic properties are not deteriorated although the spin gapless behavior could be lost at this elevated temperature. For example, for Mn$_2$CoAl at 0 K the Mn$^A$, Mn$^B$, and Co atoms show a sublattice magnetization of about $-1.5$, $2.6$, and $1.0 \mu_B$, respectively. At room temperature, these values become $-1.3$, $2.3$, and $0.8 \mu_B$, showing an absolute-value decrease of $13\%$, $11\%$, and $18\%$, respectively. The total magnetization per f.u. decreases from 2.0 $\mu_B$ at 0 K to 1.8 $\mu_B$ at room temperature showing an even smaller decrease of $10\%$. Thus, the compounds under study are adequate to be employed in spintronic/magnetoelectronic devices.

To estimate the critical temperature $T^c_{MC}$ within the Monte Carlo technique, we have plotted in Fig. 6 the susceptibility $\chi$ versus the temperature for all compounds under study. Obtained values are presented in Table II and compared with the mean-field estimation of the critical temperature $T^c_{MFA}$. As seen for all compounds $T^c_{MC}$ is much lower than the $T^c_{MFA}$. The difference ranges from 110 K for Ti$_2$VAs up to 364 K for Mn$_2$CoAl, while for the other compounds it is around 220–270 K. Note that within MFA, the critical temperature is given by the arithmetic average of all the magnon energy values with equal weight. In reality, low-energy magnons have more weight in determining the critical temperature and MFA usually overestimates experimental data by more than 20\% [61–63]. The Monte Carlo determined critical temperature does not suffer from this drawback and thus it is expected to approach the experimental values of the critical temperature.

In some magnetic compounds, an empirical trend is observed that the critical temperature increases with the magnitude of the local magnetic moments [67,70–72]. This trend is not observed here. The sum of absolute local moments (see Table I) is largest for Mn$_2$CoAl being 5.29 $\mu_B$ but the critical temperature is largest for Cr$_2$ZnSi for which this sum is only 3.34 $\mu_B$. Intuitively, we can explain this observation as follows. The critical temperature depends both (a) on the nature of the spin-dependent wave-function overlap and chemical bonds between nearest neighbors, which is a short-range property and is independent of the magnitude of the spin moments, as well as (b) the more distant interactions which are formed largely because of susceptibility effects (one atom polarizes the Fermi surface electrons and this is felt by a distant atom through the electron propagation) which largely

**FIG. 5.** (Color online) Calculated temperature dependence of the sublattice and total magnetization for (a) Mn$_2$CoAl, (b) Ti$_2$MnAl, and (c) Cr$_2$ZnSi. In the case of Ti$_2$MnAl, the total spin magnetic moment for 0 K is $-0.46 \mu_B$ since in the Monte Carlo calculations we ignore the sp atoms as well as the interstitial region (see Table I). With the arrow we denote the room temperature of 300 K. In the case of Mn$_2$CoAl, we include also the experimental results from Ref. [38].

**FIG. 6.** (Color online) Calculated temperature dependence of the susceptibility for SGSs. The maximum of the susceptibility corresponds to the critical temperature (shown in parentheses in the legends).
depend on the magnitude of the spin magnetic moments. Here, since the nearest-neighbor interactions are dominant and the long-range ones practically vanish, (a) applies but not (b).

Finally, we compare our values for $T_c$ with experimental and theoretical results on Mn$_2$CoAl compound. Our calculated MFA and Monte Carlo values are 1134 and 770 K, respectively. Meier and collaborators [37] estimated theoretically a $T_c^{\text{MFA}} = 890$ K, smaller than our MFA result. Wollman and collaborators [43] calculated $T_c^{\text{MFA}} = 985$ K, in-between our value and the value in Ref. [37] and within the more accurate spherical approximation (SPA) [44] a value of 740 K, close to our Monte Carlo value of 770 K [43]. Experimentally, for the bulklike polycrystalline film, Ouardi and collaborators [42] measured by Ouardi et al. for the bulklike polycrystalline film, Ouardi and collaborators [42] good agreement both with the SPA calculated value of 740 K [43]. Experimentally, for the bulklike polycrystalline film, Ouardi and collaborators measure for the $T_c$ a value of 720 K [38], while the experiments by Xu and collaborators on thin films of Mn$_2$CoAl gave a $T_c$ value of about 550 K [41]; this discrepancy is expected since films present critical temperatures significantly smaller that the bulk samples. Thus, our Monte Carlo value of 770 K is in good agreement both with the SPA calculated value of 740 K of Wollman et al. [43] and with the experimental value of 720 K measured by Ouardi et al. [38].

IV. CONCLUSIONS

We employed first-principles electronic-structure calculations in conjunction with the frozen-magnon method to calculate exchange interactions, spin-wave dispersion, and spin-wave stiffness constants in inverse-Heusler-based spin gapless semiconductor (SGS) compounds Mn$_2$CoAl, Ti$_2$MnAl, Cr$_2$ZnSi, Ti$_2$CoSi, and Ti$_2$VAs. We find that the magnetic behavior of the SGSs is similar to the half-metallic ferromagnetic full-Heusler alloys, i.e., the intersublattice exchange interactions play an essential role in the formation of the magnetic ground state and in determining the critical temperature $T_c$. All compounds, except Ti$_2$CoSi, possess a ferrimagnetic ground state. Due to the finite-energy gap in one spin channel, the exchange interactions decay rapidly, and hence magnetism of these SGSs can be described considering only nearest- and next-nearest-neighbor exchange interactions. The calculated spin-wave dispersion curves are typical for ferrimagnets and ferromagnets, i.e., the number of inequivalent spin-wave branches in the dispersion curves is equal to the number of magnetic atoms in the unit cell. Due to the short-range nature of the exchange interactions, the calculated spin-wave stiffness constants turn out to be larger than the elementary 3d ferromagnets.

Calculated exchange parameters are used as input to determine the temperature dependence of the magnetization and the critical temperature $T_c$ of the SGSs. We find that the $T_c$ of all compounds is much above the room temperature. The calculated magnetization curve for Mn$_2$CoAl as well as the critical temperature are in good agreement with available experimental data.

Our results suggest that, except Mn$_2$CoAl which has been already synthesized, there are other potential SGS presenting also very high Curie temperatures. In SGS materials, only one spin channel contributes to the transport properties, whereas the other spin channel allows for tunable charge-carrier concentrations. Among the five studied SGS compounds, Ti$_2$MnAl, Ti$_2$VSi, and Cr$_2$ZnSi present also zero magnetization thus creating vanishing stray fields leading to advantages that have been pointed out for antiferromagnetic spintronic devices [73,74]. Thus, we expect such fully compensated ferrimagnetic compounds to be more adequate for room-temperature spintronic/magnetoelectronic applications based on spin transport.
