The critical plasma density \( n_e \) above which the edge anomalous transport in tokamaks is dominated by drift resistive ballooning instability is found analytically. In this transport regime, the drastic increase of particle losses and drop of the edge temperature provoke a strong increase in impurity radiation, and thermal equilibrium does not exist if the density is ramped up above the ultimate limit \( n_{\text{max}} \). Because of the nonlinear character of impurity radiation, this density limit \( n_{\text{max}} \) is very close to \( n_e \), and practically does not change with the ion effective charge. The importance of the synergy between the anomalous transport and impurity radiation for the density limit phenomenon is confirmed by the results of numerical simulations.

I. Introduction.—The density limit, i.e., the maximum plasma density attainable before disruption, is one of the most fundamental operational boundaries for fusion devices [1]. Understanding this phenomenon is of extreme importance for the construction of an economically profitable thermonuclear reactor [2] since the fusion power scales quadratically with the density. On the one hand, impurity radiation increases dramatically when the density limit is exceeded [1]. Therefore it is often interpreted as a breakdown of the plasma edge thermal balance caused by an uncontrollable growth of radiation losses (see numerous citations in Ref. [1]). On the other hand, the density limit is preceded by a significant reduction of the particle confinement and an increase in the cross-field convective power losses at the plasma edge [1,3,4]. This evolution is accompanied by a principle change in the edge turbulence, and, in particular, the amplitude of low-frequency perturbations attributed to drift resistive ballooning (DRB) instability [5] increases significantly [1]. These observations are in line with the results of edge turbulence modeling [6], which predict that the particle flux should grow fast with increasing plasma collisionality. Recent computations with the code BOUT [7] have demonstrated that by approaching the experimental density limit the anomalous diffusion produced by DRB modes can grow up to \( 10^{-30} \text{m}^2/\text{s} \). In independent calculations with the transport code 2D UEDGE, such a huge diffusion led to the edge radiative instability and X-point multifaceted asymmetric radiation from the edge (MARFE) formation.

In the present Letter, a simple model for the plasma edge with prescribed dependence of the diffusion coefficient on plasma parameters is proposed. This allows one to take into account impurity radiation and convective energy losses self-consistently. It is demonstrated that the synergy of these processes is of crucial importance for the density limit phenomenon.

II. Basic equations.—Modeling of linear instabilities and turbulence [6–9] revealed different mechanisms, which could be responsible for the experimentally observed fluctuations of plasma parameters and anomalous transport of particles and energy at the plasma edge in fusion devices. "Normal" drift modes lead to a gyro Bohm type of transport coefficients, \( D_{\text{gB}} \sim [c_s^2/(\rho_e^2/L_n)]g \), where \( c_s = \sqrt{T/m_i} \) and \( \rho_e = c_s/\omega_{ce} \) are the electron Larmor velocity and Larmor radius, respectively, \( L_n = -\frac{\partial n}{\partial r} \) is the radial e-folding length of the plasma density and the factor \( g \) takes into account the dependence on other parameters. Since \( D_{\text{gB}} \sim T^{3/2} \), this channel is of importance at a high edge temperature \( T \) corresponding normally to a low enough plasma density.

With increasing density and decreasing temperature, DRB modes should become dominant in the edge transport. Indeed, \( D_{\text{DRB}} \sim (2\pi q)^2 \rho_e^2 v_{ci} E_{\text{rad}} \) [5], where \( q \) is the safety factor, \( \rho_e \) the electron Larmor radius, \( v_{ci} \) the electron-ion Coulomb collision frequency, and \( R \) the torus major radius. Therefore, \( D_{\text{DRB}} \sim n/Ln \).

A transition between two transport regimes occurs when \( D_{\text{gB}} = D_{\text{DRB}} \). This criterion is similar to the requirement of Ref. [6]: For the dominance of DRB modes, the diamagnetic parameter \( \alpha_d \sim \sqrt{D_{\text{gB}}/D_{\text{DRB}}} \) should be smaller than 1. Henceforth, the following rule will be adopted by determining the particle diffusivity \( D_\perp \) and plasma heat conductivity \( \kappa_\perp \) at the plasma edge:

\[
D_\perp = \max(D_{\text{gB}}, D_{\text{DRB}}), \quad \kappa_\perp = 3nD_\perp. \tag{1}
\]

The variation of the plasma temperature and density in time \( t \) and with the distance \( x \) from the last closed magnetic surface (LCMS) toward the plasma core is governed by one-dimensional equations for the particle and energy transport:

\[
\frac{\partial n}{\partial t} + \frac{\partial \Gamma_\perp}{\partial x} = nn_d k_i, \tag{2}
\]

\[
3\frac{\partial nT}{\partial t} + \frac{\partial q_\perp}{\partial x} = -E_t n n_d k_i - Q_{\text{rad}}. \tag{3}
\]
Here \( \Gamma_\perp = -D_\perp \frac{\partial n}{\partial m} \) and \( q_\perp = 3T \Gamma_\perp - \kappa_\perp \frac{\partial T}{\partial n} \) are the densities of particle and heat fluxes, respectively. The density of neutral particles generated by plasma recycling at the device walls, \( n_a \), is determined in a diffusion approximation [10]:

\[
\frac{\partial}{\partial x} \left[ -\frac{T}{m_i(k_i + k_{ei})n} \frac{\partial n_a}{\partial x} \right] = -k_i n_a n_a,
\]

with \( k_i \) and \( k_{ei} \) being the rate coefficients of the ionization and charge-exchange processes; \( E_i \) is the energy lost by electrons on ionization of a neutral particle.

The edge radiation comes mostly from weakly ionized species of light impurities such as carbon and oxygen with charges up to that of Li-like particles, \( Z_{Li} \). The power density of radiation losses, \( Q_{\text{rad}} \), can be estimated as \( \sum_{Z=1}^{Z_{Li}} L_Z n_Z n \) with \( L_Z \) being the cooling rate of impurity ions of the charge \( Z \). Recombination plays normally a small role in impurity particle balance at the plasma edge compared with their transport and ionization processes [11] and the densities of impurity ions, \( n_Z \), are determined from continuity equations:

\[
\frac{\partial n_Z}{\partial t} + \frac{\partial}{\partial x} \left( -D_\perp \frac{\partial n_Z}{\partial x} \right) = k_i^{-1} n_{Z-1} - k_i^0 n_Z,
\]

where \( k_i^0 \) is the ionization rate coefficient. For the density of impurity neutrals, \( n_0 \), we have

\[
\frac{\partial n_0 V_i}{\partial x} = -k_i^0 n_0,
\]

with the velocity \( V_i \) determined by the mechanism of impurity erosion.

The boundary conditions to Eqs. (2)–(6) at the LCMS, \( x = 0 \), imply (i) a given e-folding length \( \delta \) for \( n, T \), and \( n_Z \) determined by the transport in the scrape-off layer, (ii) recycling of the main particles, i.e., the balance of the neutral influx and plasma outflow, and (iii) a prescribed influx of impurity neutrals, \( \Gamma_f \). At the interface of the edge region with the core, \( x = x_c \) (i), the plasma and heat flux densities, \( n_{\text{core}} \) and \( q_{\text{core}} \), respectively, are fixed and (ii) the densities of neutrals and of low-\( Z \) radiant impurity species reduce to zero.

III. Analytical consideration.—For a qualitative analysis, we consider stationary states with \( \frac{\partial n_{\text{core}}}{\partial T} = 0 \). An integral of Eq. (3) over the width of the edge layer gives a power balance for this region:

\[
q_{\text{core}} = 3\Gamma_p T_{L} + \Gamma_p E_i + \kappa_{\perp} \frac{T_{L}}{\delta} + q_{\text{rad}},
\]

Here the first term is the convective energy losses, the second one is losses on ionization of recycling neutrals, the third one is with plasma heat conduction, and the last one is with impurity radiation. The density of the charge particle flux through the LCMS, \( \Gamma_p \), can be estimated as \( D_\perp (n_{\text{core}}/L_p) \), where the e-folding length of the density at the plasma edge is determined by the penetration depth of recycling neutrals. From Eq. (4), we obtain

\[
L_p = 1/(\sigma_s n_{\text{core}}) \text{ with } \sigma_s = \sqrt{m_i(k_i + k_{ei})/T}
\]

and thus

\[
\Gamma_p = \alpha D_\perp (n_{\text{core}}, T) n_{\text{core}}^2 \sigma_s(T).
\]

The numerical factor \( \alpha \) is due to the density dependence of the particle diffusivity \( D_\perp \) [10]. For that given by Eq. (1), \( \alpha = 0.1 \) is a reasonable estimate. A numerical modeling (see Ref. [10] and the section below) predicts that the plasma temperature at the LCMS, \( T_L \), is by a factor of 2 lower than the mean temperature in the edge region, \( T \).

In order to assess the flux density of radiation losses, \( q_{\text{rad}} = \int Q_{\text{rad}} dx \), we take into account that the cooling rates of all radiant species with \( Z \leq Z_{Li} \) are close to each other [12] and one can introduce an effective \( L_{\text{rad}} \). Therefore \( Q_{\text{rad}} = n_{\text{rad}} L_{\text{rad}} \), where

\[
n_{\text{rad}} = \sum_{Z=1}^{Z_{Li}} n_Z.
\]

An equation for \( n_{\text{rad}} \) results from the summation of the continuity equations (5) over \( Z \). By taking into account that in the region where Li-like particles are ionized they dominantly contribute to \( n_{\text{rad}} \) [11], one gets

\[
\frac{\partial}{\partial x} \left( -D_\perp \frac{\partial n_{\text{rad}}}{\partial x} \right) \approx k_i^0 n_0 - k_i^0 n_{\text{rad}}.
\]

By replacing the plasma density and temperature profiles with their characteristic values in the edge region, Eqs. (6) and (9) can be integrated analytically [13]. With the solution found, we obtain

\[
q_{\text{rad}} = \Gamma_p \frac{L_{\text{rad}}}{k_i^0 \epsilon_{\text{rad}}} = \frac{l_0}{l_0 + l_0},
\]

where \( l_0 = V_i/(k_i^0 n_{\text{core}}) \) and \( l_0 = \sqrt{D_\perp / (k_i^0 n_{\text{core}})} \) are the penetration depths of impurity neutrals and radiant species, respectively.

Thus, for given heat flux and plasma densities at the core boundary, Eq. (7) provides a nonlinear algebraic equation for the edge temperature. As an example, Fig. 1 shows \( T \) versus \( n_{\text{core}} \) computed for the parameters of Texas Experimental Tokamak (TEXT) [4]: \( R = 1 \text{ m}, B_T = 2.8 \text{ T}, q_{\text{core}} = 3.5 \text{ W/cm}^2 \), \( q = 3 \). First, consider the curve 1 found without impurity radiation. One can see that at \( n_{\text{cr}} = 0.8 \times 10^{14} \text{ cm}^{-3} \) there is a principle change in the density dependence of the temperature. This critical condition corresponds to the transition into the regime with the edge transport dominated by DRB modes, i.e., \( D_{\phi B} = D_{\text{DREB}} \). The convective loss term dominates in the right-hand side of Eq. (7) and, by making use of Eq. (8) with the estimate for \( L_p \) given above, one gets the dependence of \( n_{\text{cr}} \) on other parameters:

\[
n_{\text{cr}} \sim q_{\text{core}}^{0.24} B_T^{0.48} q_{\text{core}}^{0.6} q_{\text{core}}^{10.6} q_{\text{core}}^{0.24} B_T^{10.17},
\]

where \( I_p \) is the plasma current. For Ohmically heated plasmas with \( q_{\text{core}} \sim I_p \), the current dependence of \( n_{\text{cr}} \) is close to Greenwald scaling [3], \( n_{\text{core}} \sim I_p \). With additional
heating, \( q_{\text{core}} \) is independent of the current and one gets \( n_{\text{max}} \sim T_0^{0.6} \). The deviation from the Greenwald scaling is probably due to neglected parametric dependence of the factor \( g \) in \( D_{EB} \).

When \( n_{\text{max}} \) is exceeded, \( T \) drops and particle flux grows very fast with the density. Indeed, \( \sigma_c \) changes weakly for \( T > 15 \text{ eV} \) and \( L_p \sim 1/n_{\text{core}} \); besides \( \rho^2_c \sim T \) and \( \nu_{ei} \sim n/T^{3/2} \). Thus, \( D_{\text{DRB}} \sim n^2/\sqrt{T}, \Gamma_p \sim n^{4/7}/T \), and, by taking into account that the convective energy loss dominates in the total one, i.e., \( q_{\text{core}} = 3 \Gamma_p T \), one gets \( T \sim n_{\text{core}} \) and \( \Gamma_p \sim n_{\text{core}}^{8/3} \). As a result, impurity radiation can rise dramatically because (i) the influx of impurities is normally proportional to \( \Gamma_p \) and (ii) the lifetime of radiant particles increases when their ionization rate drops with decreasing temperature. The curve 2 in Fig. 1 shows \( T \) versus \( n_{\text{core}} \) calculated by taking into account the radiation of carbon impurity released into the plasma with \( \Gamma_I = 0.02 \Gamma_p \). The temperature independent erosion coefficient was assumed here by implying that at low \( T \) carbon physical sputtering [14] is replaced by chemical erosion [15]. One can see that no stationary states exist for \( n_{\text{core}} > n_{\text{max}} \); i.e., the latter is the density limit set in by radiation. However, the extreme proximity of \( n_{\text{max}} \) to \( n_{\text{cr}} \) shows the principle importance of the transition to the DRB dominated transport regime for the level of \( n_{\text{max}} \).

The curve 3 in Fig. 1 demonstrates \( T(n_{\text{core}}) \) computed by assuming \( D_{\perp} = D_{EB} \) in the whole parameter range. One can see that the maximum density is here significantly higher than with \( D_{\perp} \) from Eq. (1). The density limit at \( n_{\text{max}} \) is close to an experimental one of \( 0.8 \times 10^{14} \text{ cm}^{-3} \) [4].

Normally, from the fact that the density limit is ultimately owing to radiation, one would guess that the absolute value of \( n_{\text{max}} \) should be sensitive to the ion effective charge \( Z_{\text{eff}} \). This is, however, not the case. By increasing the carbon erosion coefficient by an order of magnitude from 0.02 to 0.2, \( Z_{\text{eff}} \) was changed in the range 1.1–2. That led to an alteration of \( n_{\text{max}} \) from 0.82 to \( 0.74 \times 10^{14} \text{ cm}^{-3} \), i.e., by 10% only. The cause is a very nonlinear variation of \( q_{\text{rad}} \) due to \( k_{\text{rad}} \sim \exp[-(I_{Z_{\text{eff}}}/T)] \), where \( I_{Z_{\text{eff}}} \) is the ionization potential of Li-like impurity ions [11]. For \( n_{\text{core}} < n_{\text{cr}} \) where \( T \) is high enough \( q_{\text{rad}} \) is less than 10% of \( q_{\text{core}} \). In the DRB transport regime, \( T \) drops and \( q_{\text{rad}} \) increases very fast with \( n_{\text{core}} \). Namely, the nonlinear character of \( q_{\text{rad}} \) behavior but not its absolute level is responsible for the bifurcation at \( n_{\text{max}} \), where radiation losses are 20%–25% of the input power. Thus, similarly to the Greenwald limit [1,3], \( n_{\text{max}} \) is practically independent of \( Z_{\text{eff}} \) and radiation.

IV. Results of numerical modeling.—In order to validate the results of our analytical consideration, Eqs. (2)–(6) were integrated numerically. Figure 2(a) shows temperature profiles attained in stationary states for different \( n_{\text{core}} \) without impurity radiation. One can see the noticeable change in the profile and reduction of the temperature at the LCMS when \( n_{\text{core}} \) is ramped up from

![FIG. 1. Edge temperature versus core density computed without (curve 1), with (curve 2) impurity radiation, and under assumption \( D_{\parallel} = D_{EB} \) in the whole parameter range (curve 3). (The broken branches of curves 2 and 3 correspond to unstable states.)](image-url)
0.8 to $0.9 \times 10^{14} \text{ cm}^{-3}$. This indicates a transition in the edge transport, which also manifests itself in the increase of the particle flux shown in Fig. 2(b).

The effect of radiation was simulated by starting the release of impurity neutrals after establishment of a stationary equilibrium. For $n_{\text{core}} = 0.8 \times 10^{14} \text{ cm}^{-3} \leq n_{\text{cr}}$, this did not lead to any significant change in the temperature profile even after 1 s. When $n_{\text{core}}$ was increased up to $0.9 \times 10^{14} \text{ cm}^{-3} \geq n_{\text{cr}}$, the impurity release led to a very fast time evolution of the temperature and radiation power density profiles shown in Fig. 3. Finally, this evolution terminates into a radiative collapse of the plasma.

V. Conclusion.—The model proposed predicts that the edge transport becomes dominated by drift resistive ballooning modes when the plasma density exceeds the critical level $n_{\text{cr}}$. As a result, the particle losses increase and the edge temperature drops strongly, in agreement with observations done on many tokamaks in the vicinity of density limit [1,3,4]. Consequently, the radiation losses from impurities increase drastically and, according to the analytical consideration, stationary states do not exist if the plasma density is raised above the limit $n_{\text{max}}$ slightly higher than $n_{\text{cr}}$. Numerical modeling shows that with usual impurities such as carbon a radiative collapse of the plasma occurs directly when $n_{\text{cr}}$ is exceeded.

In this Letter, the radial radiative collapse has been considered as a density limiting phenomenon. In divertor machines, however, poloidally asymmetric X-point MARFE normally develops first. For a consideration of this case, a further development of the model is needed. Qualitatively, one could expect that $n_{\text{max}}$ approaches even closer to $n_{\text{cr}}$. On the contrary, if the release of impurity diminishes strongly with decreasing temperature, e.g., in the case of pure physical sputtering, $n_{\text{max}}$ noticeably exceeding $n_{\text{cr}}$ can be expected. This would explain the increase of the density limit under conditions of wall boronization and siliconization [16].
