(Received 11 June 2007; revised manuscript received 4 September 2007; published 13 November 2007)

Ab initio results for the static (linear) elasto-optic or Pockels constants $p_{ij}$ and (nonlinear) constants $p_{ijk}$ for the fluorite systems CaF$_2$ and BaF$_2$ are presented from investigating the dielectric tensor under various forms and sizes of strain. The contribution to the Pockels constant $p_{44}$ from the internal strain is important reducing the “bare” value by a factor of about 2 or more.

I. INTRODUCTION

CaF$_2$ and BaF$_2$ are strongly ionic, wide-band-gap materials raising interest in their use for precision vacuum ultraviolet (vuv) lithography. The steadily advancing miniaturization of integrated circuits and the aim of producing microchips with increasingly small sizes needs a reduction of the wavelengths used in lithography processes from the visible to the ultraviolet ($\approx$400 nm) and the vacuum ultraviolet ($\approx$200 nm) region. A demand arises for new materials for lenses with a band gap wider and transmission higher than the commonly used glassy materials. In this context, CaF$_2$ with its large band gap is the material of choice, and BaF$_2$ with its similar properties constitutes an alternative material, since sizable and qualitatively good crystals can be produced. A perfect cubic symmetry is the requirement for isotropic optical properties.

For a defined optical system the knowledge of changes of the refractive index with temperature or volume is essential. Deviations of the index of refraction from the ideal ground-state value can lead to a change of quality. One issue is thereby the intrinsic birefringence induced by the spatial dispersion coming from a small optical anisotropy at nonzero energy which is studied, e.g., in Refs. 2 and 3.

Another key question is the behavior of the optical properties under strain. The thermal expansion of a material or the volume reduction due to pressure are two possible forms of strain. This aspect is the topic of the present paper. The change of the high-frequency dielectric constant, namely the elasto-optical constants, is calculated resulting from various applied strains. Despite the technological interest at vuv energies we restrict ourselves to the static Pockels constants, i.e., those at low energies compared to electronic-gap energies but high energies compared to phonon energies, and demonstrate the role of nonlinear effects.

II. NUMERICAL DETAILS

Both systems, CaF$_2$ and BaF$_2$, crystallize in the face-centered cubic fluorite structure ($Fm\bar{3}m$) with three atoms in the elementary cell with the alkaline-earth ion at (0,0,0) and the F$^-$ ions at $\pm \frac{1}{2}(1,1,1)a$.

The electronic and structural properties of the ground state have been determined within the methods of density functional theory in the local-density approximation (LDA). For the calculation of the Pockels constants we have used the pseudopotential method as implemented in the ABINIT code which allows one to consider the effects of macroscopic electric fields and thus the high-frequency (low-energy) dielectric constant. Ground-state and dynamical properties have been calculated elsewhere for the sake of comparison for CaF$_2$ and BaF$_2$ with different ab initio program packages, showing the reliability of the method used.

For both substances we have used the Hartwigsen-Goedcker-Hutter pseudopotential, which proved to give better dielectric and dynamical results than, e.g., Troullier-Martins or combinations of other available pseudopotentials. For CaF$_2$ we have used an energy cutoff of 110 Ha and a 4$^4$-point mesh leading to a precision of 10$^{-3}$ Ha in the ground-state energy. For BaF$_2$ an energy cutoff of 100 Ha and the same k-point mesh leading to a precision of 10$^{-3}$ Ha in the ground-state energy. The resulting ground-state lattice constants and high-frequency dielectric constants are listed in Table I. As in many other cases the LDA result slightly underestimates the experimental value of the lattice constant and overestimates the dielectric constant, see Table I.

III. CALCULATION OF THE POCKELS CONSTANTS

For small distortions the change in the dielectric function tensor $\epsilon$ is linear in the strain, and the (linear) Pockels constants $p_{a\beta\gamma\delta}$ are defined by

$$\delta\epsilon_{a\beta} = \epsilon_{a\beta} - \epsilon_{a,\beta} = -\varepsilon_{c} p_{a\beta\gamma\delta} \delta\gamma\delta,$$

(1)

where the Einstein summation convention is used.

In this work we investigate only the symmetrical part of the strain tensor,

$$e_{a\beta} = \frac{1}{2} \left( \frac{\partial u_{a}}{\partial \xi_{\beta}} + \frac{\partial u_{\beta}}{\partial \xi_{a}} \right).$$

Calculations have been performed with various finite but small strains with respect to the equilibrium structure to yield the corresponding high-frequency dielectric constants. Standard procedures include isotropic and uniaxial pressures along the cube axes for the determination of $p_{11}$ and $p_{12}$ and uniaxial pressures along a face or space diagonal for that of $p_{44}$.

We have calculated the dielectric constant for six symmetrically different strains. It should be kept in mind that the theoretical equilibrium dielectric constant is somewhat larger by the same amount.

IV. NONLINEAR CONTRIBUTIONS

The Pockels constants will be given in the Voigt notation. For a cubic system there are three symmetrically inequivalent, nonvanishing elements of a fourth-order (linear) tensor

$$\epsilon_{xxx} = \epsilon_{111}, \quad \epsilon_{xxy} = \epsilon_{112}, \quad \epsilon_{xxz} = \epsilon_{114},$$

and nine sixth-order (nonlinear) tensor elements,

$$\epsilon_{112}, \quad \epsilon_{122}, \quad \epsilon_{113}, \quad \epsilon_{123}, \quad \epsilon_{166}, \quad \epsilon_{144},$$

$$\epsilon_{566}, \quad \epsilon_{661}, \quad \epsilon_{444}.$$  

In contrast to the six sixth-order tensor elements of the nonlinear elastic constants, here relations like $\epsilon_{441} = \epsilon_{414}$ are not true since the first index refers to the derivative with respect to the electric field components, while the latter two indices refer to the derivatives with respect to strains.

Expansion in terms of the strain leads to

$$\delta\epsilon_{a\beta} = \epsilon_{a\beta\gamma\delta} \delta\gamma\delta + \frac{1}{2} \epsilon_{a\beta\gamma\delta} \delta\gamma\delta \delta\gamma\delta$$

and in particular, in Voigt notation (and for symmetric strains only),

$$\delta\epsilon_{1} = \epsilon_{111} \delta e_{1} + \epsilon_{112} \delta e_{2} + \epsilon_{114} \delta e_{4} + \frac{1}{2} \epsilon_{111} \delta e_{1}^{2} + \frac{1}{2} \epsilon_{112} \delta e_{2}^{2} + \epsilon_{114} \delta e_{4}^{2}$$

$$+ \epsilon_{122} \delta e_{2} (\delta e_{2} + \delta e_{3}) + \epsilon_{123} \epsilon_{2} \epsilon_{3} + 2 \epsilon_{144} \delta e_{4}^{2} + 2 \epsilon_{166} \delta e_{5}^{2} + \epsilon_{566} \delta e_{6}^{2},$$

(2)

V. RESULTS

Rather than taking differentials we have taken differences, and thus we have been led to compute to the nonlinear in addition to the linear Pockels constants. In order to obtain the single Pockels constants rather than their combinations we considered various types of strain which involve different combinations of the Pockels constants.

In general we have calculated the dielectric constant at equilibrium and two different strains (of the same symmetry); then we have fitted a parabola through these data sets from which the linear and second-order changes can be extracted. In order to circumvent numerical noise we have used strains of the order of a percent. This may seem large, but the results for different choices of the strains turn out to be rather consistent. In fact, in almost all cases we have used the results from the different choices to estimate the numerical error bars. The results will be given in rounded numbers, even though the computations themselves have been done with a larger number of digits.

A. Strictly uniaxial strain ($T_{1e}$ symmetry)

In this section we investigate a compression (or extension) along only one cube axis. This type of strain may be unfeasible in an experiment since it is usually accompanied by an extension (or compression) perpendicular to it; but this strain is quite interesting from a theoretical point of view since it leads to an independent and simultaneous determination of $p_{11}$ and $p_{12}$.

From Eqs. (2) and (3) and with only the strain-tensor element $\delta e_{zz} = \delta e_{3} = e$ not vanishing we obtain to second order in $e$

$$\delta\epsilon_{1} = \delta e_{2} = \epsilon_{122} e_{2} + \frac{1}{2} \epsilon_{122} e_{2}^{2},$$

(5)

$$\delta\epsilon_{5} = \epsilon_{111} e_{1} + \frac{1}{2} \epsilon_{111} e_{1}^{2},$$

(6)

$$\delta\epsilon_{3} = \delta\epsilon_{5} = \delta\epsilon_{6} = 0.$$  

I. BaF$_2$

The results for BaF$_2$ from a quadratic fit to the results of strains $e_{3} = \epsilon_{zz} = \pm 0.05$ as well as with $e_{3} = \pm 0.2$ together with the equilibrium data ($e_{3} = 0$) (and all other components vanishing) are very similar; the mean is

$$\delta\epsilon_{4} = 2 \epsilon_{44} e_{4} + 4 \epsilon_{456} e_{5} e_{6} + 2 \epsilon_{441} e_{4} e_{1} + 2 \epsilon_{661} e_{4} (e_{2} + e_{3})$$

(3)

and cyclic. The linear and nonlinear Pockels constants are then given by

$$d\epsilon_{i}^{-1} = -\frac{1}{\epsilon_{0}} (e_{ij} + e_{ijk} e_{k}) = p_{ij} + p_{ijk} e_{k}.$$
For later use in Sec. V D we note the derived numbers of \( p \) out square brackets

\[
\text{STATIC POCKELS CONSTANTS} \quad \pi_{ij}
\]

the contribution to the strains used in our calculations, in particular

\[\text{Reference 17, pressure dependence of refractive index.}\]

\[\text{Reference 16, dipole-dipole model.}\]

\[\text{Ab initio calculation using ABINIT, this work. Error bars are from numerical uncertainties.}\]

\[\text{Reference 15.}\]

\[\text{Reference 14, calculated from piezobirefringence data at 589.3 nm cited therein.}\]

\[\text{Reference 13, Brillouin scattering at 632.8 nm.}\]

\[\text{Reference 12, as cited in Ref. 18.}\]

\[\delta \varepsilon_3 = -0.316(4)e + 1.21(6)e^2,\]

\[\delta \varepsilon_1 = -1.46(4)e + 2.19(4)e^2.\]

The derived numbers of \( p_{11} \) and \( p_{12} \) appear in Table II (without square brackets) and those of \( p_{111} \) and \( p_{122} \) in Table III. For later use in Sec. V D we note

\[
\frac{1}{2} \varepsilon_{111} = 1.21(6), \tag{7}
\]

\[
\frac{1}{2} \varepsilon_{122} = 2.19(4). \tag{8}
\]

The relative contribution of the nonlinearities is appreciable for the strains used in our calculations, in particular the contribution to \( \varepsilon_{11} \) and \( p_{11} \).

\[\delta \varepsilon_3 = +0.125(8)e + 0.93(5)e^2,\]

\[\delta \varepsilon_1 = -1.15(3)e + 1.91(4)e^2.\]

For later use in Sec. V D we note

\[
\frac{1}{2} \varepsilon_{111} = 0.93(5), \tag{9}
\]

\[
\frac{1}{2} \varepsilon_{122} = 1.91(4). \tag{10}
\]

As for BaF\(_2\) the contribution of the nonlinearities is appreciable for the strains used in our calculations. To our sur-

prise, the sign of the value for \( p_{11} \) for CaF\(_2\) turns out to be opposite to the experimental one. We will come back to this finding at the end of the paper.

3. Strain-induced birefringence

For the strain-induced birefringence \( \epsilon_i - \epsilon_{i0} = \delta \epsilon_i - \delta \epsilon_{i0} \) we obtain the values 1.15(4)\( \epsilon \) for BaF\(_2\) and 1.28(4)\( \epsilon \) for CaF\(_2\). This is to be compared with the theoretical values \( = 1.1 \epsilon \) and \( = 1.15 \epsilon \), respectively, from Ref. 1 for their \( K_{11} \) and \( K_{12} \) as read off their figures at \( E \rightarrow 0 \). At \( E = 2.2 \) eV, the experimental values of Ref. 1 are 0.72(3) and 0.78(8), respectively.

B. Homogeneous strain (\( A_{1g} \) symmetry)

This case corresponds to hydrostatic conditions. For all diagonal strain-tensor elements equal \( (\epsilon_{xx} = \epsilon_{yy} = \epsilon_{zz} = \epsilon \) and zero off-diagonal elements) we obtain from Eq. (2)

\[
\delta \epsilon_i = \delta \epsilon_x = \delta \epsilon_y = (\epsilon_{11} + 2 \epsilon_{12}) e + \left( \frac{1}{2} \epsilon_{111} + \epsilon_{122} + 2 \epsilon_{112} + \epsilon_{123} \right) e^2. \tag{11}
\]

1. BaF\(_2\)

From the lattice constants 5.9, 6.0, and 6.2 Å and quadratic fits to three different combinations of two of these with the equilibrium lattice constant 6.05 Å we find

\[
\delta \epsilon_1 = -3.139(3) \epsilon + 6.9(2) \epsilon^2 \tag{12}
\]

and by comparison with Eq. (11)

\[
p_{11} + 2p_{12} = 0.5139(5), \tag{13}
\]

\[
p_{111} + 2p_{122} + 4p_{112} + 2p_{123} = -2.26(6), \tag{14}
\]

while from \( p_{11} \) and \( p_{12} \) of Sec. V A above for uniaxial strain along \( z \) we find

\[
p_{11} + 2p_{12} = 0.53(1)
\]

in reasonable agreement (within 3%) with each other. (This latter is the number in square brackets in Table II.) This is also in agreement with the result of Ref. 1, Fig. 9, where \( \delta \epsilon_1 \approx -3 \epsilon \) at low energies. The nonlinear constants for the two different strain symmetries must differ, since they contain different combinations of the \( p_{ijk} \).

2. CaF\(_2\)

From the lattice constants 5.33 (equilibrium), 5.3, and 5.4 Å and a quadratic fit we find

\[
\delta \epsilon_1 = -2.097 \epsilon + 5.078 \epsilon^2 \tag{15}
\]

and

\[
p_{11} + 2p_{12} = 0.3729(4), \tag{16}
\]

\[
p_{111} + 2p_{122} + 4p_{112} + 2p_{123} = -1.81(5), \tag{17}
\]

assuming a numerical error as for BaF\(_2\), namely 0.1% for the linear and 3% for the nonlinear result, while from the data for strictly uniaxial strain along \( z \) we find

\[
p_{11} + 2p_{12} = 0.386(13).
\]

The linear Pockels constants from the two symmetrically different strains agree within 3%. This is also in agreement with the data of Ref. 1, Fig. 7, where \( \delta \epsilon_1 \approx -2.3 \) (as compared to our value of 2.1) at low energies. The nonlinear constants must differ as mentioned above; they will be considered further below in Sec. V E.

C. Shear strain (\( E_3 \) symmetry)

This corresponds to uniaxial conditions at constant volume with pressure along a cube axis. We choose pressure along the \( z \) axis; with \( \epsilon_1 = \epsilon_2 = -\frac{1}{2} \epsilon_3 = \epsilon \) and all other components vanishing in Eq. (2) the two different components \( \epsilon_1 = \epsilon_2 \) and \( \epsilon_3 \) have different nonlinearities,

\[
\delta \epsilon_1 = -2(\epsilon_{11} - \epsilon_{12}) e + (2 \epsilon_{111} + \epsilon_{122} - 4 \epsilon_{112} + 4 \epsilon_{123}) e^2, \tag{18}
\]

\[
\delta \epsilon_3 = -2(\epsilon_{11} - \epsilon_{12}) e + (2 \epsilon_{111} + \epsilon_{122} - 4 \epsilon_{112} + 4 \epsilon_{123}) e^2, \tag{19}
\]

I. BaF\(_2\)

With a strain of \( \epsilon_1 = \epsilon_{xx} = \pm 0.02 \) (and \( \epsilon_1 = 0 \)) we obtain

\[
\delta \epsilon_1 = 1.1032 \epsilon + 9.501 \epsilon^2, \tag{20}
\]

\[
\delta \epsilon_3 = -2.209 \epsilon + 9.400 \epsilon^2, \tag{21}
\]

and

\[
p_{111} + 5p_{122} - 2p_{112} - 4p_{123} = -3.108 \text{ from } \epsilon_1, \tag{22}
\]

\[
4p_{111} + 2p_{122} - 8p_{112} + 2p_{123} = -3.078 \text{ from } \epsilon_3. \tag{23}
\]

The average of the linear constants is

\[
p_{11} - p_{12} = 0.1807(2),
\]

while the numbers of Sec. V A above yield

\[
p_{11} - p_{12} = -0.187(2). \tag{24}
\]

(This is the number in square brackets in Table II.) Thus the calculations with strains of the three different symmetries \( T_{1g}, A_{1g}, \) and \( E_3 \) give very consistent results for the two (linear) Pockels constants \( p_{11} \) and \( p_{12} \) and their combinations. Further considerations concerning different combinations of \( p_{11} \) and \( p_{12} \) will be made in Sec. V D.

2. CaF\(_2\)

Analogously to the case of BaF\(_2\) we obtain

\[
\delta \epsilon_1 = 1.231 \epsilon + 7.691 \epsilon^2, \tag{25}
\]

\[
\delta \epsilon_3 = -2.458 \epsilon + 10.317 \epsilon^2, \tag{26}
\]

\[
p_{11} + 2p_{12} = 0.386(13).
\]
STATIC POCKELS CONSTANTS $p_{ij}$ AND $p_{ijk}$…

\[ p_{111} + 5p_{122} - 2p_{112} - 4p_{123} = - 2.736 \quad \text{from } \epsilon_1, \quad (27) \]

\[ 4p_{111} + 2p_{122} - 8p_{112} + 2p_{123} = - 3.670 \quad \text{from } \epsilon_3. \quad (28) \]

The average of the linear constant is

\[ p_{11} - p_{12} = - 0.2187(2), \quad (29) \]

and the numbers from Sec. V A yield the same, although less precise result

\[ p_{11} - p_{12} = - 0.226(7) \]

for the linear term.

D. $A_{1g}$ and $E_g$ data combined

The combination of the $A_{1g}$ and $E_g$ data can be used to determine the constants $p_{11}$ and $p_{12}$. These results enter Table II in square brackets and seem to be somewhat more precise than the directly calculated values of Sec. V A.

As a further check of consistency of the Pockels constants $p_{11}$ and $p_{12}$, we have investigated a strain of still another symmetry, namely with $\epsilon_1 = - \epsilon_2 = - \epsilon_3 = \epsilon$ and all other components vanishing. From Eq. (2) one has

\[ \delta \epsilon_1 = \delta \epsilon_2 = \epsilon_{11} e + \frac{1}{2} (\epsilon_{111} + 2 \epsilon_{112} - 2 \epsilon_{123}) \epsilon^2, \quad (30) \]

\[ \delta \epsilon_3 = (- \epsilon_{11} + 2 \epsilon_{12} - 4 \epsilon_{112} + 2 \epsilon_{123}) \epsilon^2, \quad (31) \]

which can be written as

\[ \delta \epsilon_1 = \delta \epsilon_2 = - \frac{1}{3} \delta \epsilon_3^{A_{1g}} + \frac{2}{3} \delta \epsilon_3^{E_g} - \epsilon_{122} \epsilon^2, \quad (32) \]

\[ \delta \epsilon_3 = \frac{1}{3} \delta \epsilon_3^{A_{1g}} + \frac{2}{3} \delta \epsilon_3^{E_g} - \epsilon_{111} \epsilon^2. \quad (33) \]

The results from a direct computation can be compared to the results derived from the data of Secs. V A–V C. With $\epsilon = 0.03$ we obtain for BaF$_2$

\[ \delta \epsilon_1 = - 0.00561, \]

\[ \delta \epsilon_3 = - 0.07009 \]

directly and

\[ \delta \epsilon_1 = - 0.0055(4), \]

\[ \delta \epsilon_3 = - 0.0700(5) \]

as derived from Eqs. (7), (8), (12), (20), and (21). Likewise, we find by direct computation for CaF$_2$

\[ \delta \epsilon_1 = + 0.00635, \]

\[ \delta \epsilon_3 = - 0.06410, \]

and from Eqs. (15), (25), (26), (9), and (10) with $\epsilon = 0.03$

For this symmetry we did not investigate other values of $\epsilon$ since the different strains led to essentially identical results, demonstrating the consistency of the results from different strains.

E. Nonlinear $T_{2g}$, $A_{1g}$, and $E_g$ data combined

We consider the results for the $T_{2g}$ data $p_{111}$ and $p_{122}$ from Sec. V A as rather reliable, since also the linear terms are quite consistent. Taking these $T_{2g}$ data as given independently and as granted there remain the three equations (14), (22), and (23) (in the case of BaF$_2$) from the $A_{1g}$ and $E_g$ data for the two constants $p_{112}$ and $p_{123}$. To be on the safe side we assume an error bar of 5% for the $E_g$ nonlinearity, somewhat larger than the 3% error bars for the $A_{1g}$ nonlinearity. In the way described we obtain the data for $p_{112}$ and $p_{123}$ as in Table III for BaF$_2$ and likewise for CaF$_2$.

F. Shear strains ($T_{2g}$ symmetry)

We have investigated two different distortions,

\[ e_{[111]} = e_{[111]} \begin{pmatrix} 0 & 1 & 1 \\ 1 & 0 & 1 \\ 1 & 1 & 0 \end{pmatrix} \]

and

\[ e_{[110]} = e_{[110]} \begin{pmatrix} 0 & 1 & 0 \\ 1 & 0 & 0 \\ 0 & 0 & 0 \end{pmatrix}, \]

for uniaxial strain along the [111] and [110] directions, respectively. To second order one has from Eqs. (2) and (3)

\[ \delta \epsilon_1 = \delta \epsilon_2 = \delta \epsilon_3 = 0 + 2 \epsilon_{444} + 4 \epsilon_{666} e_{[111]}^2, \quad (34) \]

\[ \delta \epsilon_4 = \delta \epsilon_5 = \delta \epsilon_6 = 2 \epsilon_{444} e_{[111]}^2 + 4 \epsilon_{456} e_{[111]}^2 \quad (35) \]

for the [111] case and

\[ \delta \epsilon_1 = 0 + 2 \epsilon_{666} e_{[110]}^2, \quad (36) \]

\[ \delta \epsilon_2 = \delta \epsilon_3 = 0 + 2 \epsilon_{444} e_{[110]}^2, \quad (37) \]

\[ \delta \epsilon_6 = 2 \epsilon_{444} e_{[110]}^2 + O(\epsilon^3), \quad (38) \]

\[ \delta \epsilon_4 = \delta \epsilon_5 = 0 \quad (39) \]

for the [110] case.

For BaF$_2$ and CaF$_2$ it turns out that the internal strain, i.e., the shift of the F atoms from their symmetry positions \( \pm \frac{1}{2}(1,1,1) \), gives a very important contribution to $p_{44}$. The internal strain itself is considered in Sec. V G.

I. BaF$_2$

We have used the values $\pm 0.025$ and $0.05$ (and $\epsilon = 0$) for $e_{[111]}$ and $e_{[110]}$, and from three quadratic fits we find...
The values for $p_{44}$ from the two different strains come out almost identical; the average is given in Table II.

As expected from Eq. (38), the nonlinear contribution to $p_{44}$ for the strain along the [110] direction nearly vanishes. Also as expected from Eqs. (34), (36), and (37), the linear term of the diagonal elements $\delta e_1$ and $\delta e_3$ nearly vanishes. From the [111] data we find $p_{44}$, and from the [110] data we find $p_{166}$ and $p_{144}$. See Table III. These [110] numbers yield

$$p_{144} + 2p_{166} = -0.578(6),$$

while the [111] results, compared with Eq. (34), are much less precise,

$$p_{144} + 2p_{166} = -0.46(11),$$

with barely overlapping error bars.

Neglecting the internal strain the values of $p_{44}$ would be too large by a factor of between 2 and 3 for $e_{[111]}$ and of about 4 for $e_{[110]}$. More details of the internal-strain parameter will be considered in Sec. V G.

2. CaF$_2$

The qualitative findings for CaF$_2$ are similar to those of BaF$_2$. With the values $\pm 0.025$ for $e_{[110]}$ and $\pm 0.025$ and 0.05 for $e_{[111]}$ we find

$$\delta e_1 = -0.01(2)e_{[111]} + 3.5(1.7)e_{[111]}^2,$$

$$\delta e_6 = -0.351(5)e_{[111]} - 1.6(1)e_{[111]}^2,$$

$$\delta e_1 = +0.0005e_{[166]} + 0.737e_{[110]}^2,$$

$$\delta e_3 = -0.0011e_{[110]} + 3.592e_{[110]}^2,$$

$$\delta e_6 = -0.357e_{[110]} + 0.059e_{[110]}^2.$$

We assume an error of 1% for $p_{44}$ from the [110] result and of about 1% for $p_{144}$ and $p_{166}$ as found for BaF$_2$. From the [110] data we obtain

$$p_{144} + 2p_{166} = -0.450(4),$$

while from the nonlinear [111] results for $\delta e_1$ we find the less precise value

$$p_{144} + 2p_{166} = -0.31(15)$$

with overlapping error bars. Without the internal strain the values of $p_{44}$ would be too large by a factor of about 1.8 for $e_{[111]}$ and of about 2 for $e_{[110]}$.

3. Strain-induced birefringence

For the birefringence $e_i - e_j = \delta e_i$ induced by the [111] strain we obtain the values $\delta e_i = -0.26(1)e_6$ for BaF$_2$ and $\delta e_i = -0.351(5)e_6$ for CaF$_2$ (to first order in $e_6$). Our values are larger by factors of about 2 and 3, respectively, than the low-energy experimental values shown in Ref. 1, despite the fact that our results for $p_{44}$ are in good agreement with the experimental data, see Table II. The theoretical and experimental values of Ref. 1 agree well for CaF$_2$ but differ strongly for BaF$_2$, even with a wrong sign. (This has led the authors of Ref. 1 to consider the internal-strain parameter as a fit parameter, see Sec. V G.)

G. Internal-strain parameter

The earth-alkaline atom at (0,0,0) is in the centrosymmetric octahedral nearest-neighbor surrounding, and the F atoms at $\pm 1/2(1,1,1)a$ are positioned in the noncentrosymmetric tetrahedral surrounding. Except for isotropic strain or uniaxial strain along a cube axis, the F atoms are, therefore, shifted off the (homogeneously distorted) center positions under general strain, the displacement components (in units of the lattice constant $a$) being given as

$$u_a = -\frac{1}{4}\bar{\zeta}_{\alpha\beta\gamma}e_{\alpha\beta\gamma}$$

with the internal-strain displacement-tensor elements $\bar{\zeta}_{\alpha\beta\gamma}$. For the fluorite structure 21 of the $3 \times 3 \times 3 = 27$ elements of the internal-strain tensor vanish, namely those with any two or more equal indices, and the six nonvanishing elements with three different indices are all equal,

$$\bar{\zeta}_{xyz} = \zeta$$

(and all permutations of the indices).

It turns out that $p_{44}$ strongly depends upon the size of the internal strain; for a numerical study of this dependence see, e.g., Ref. 1.

I. BaF$_2$

The $e$ component of the internal-strain displacement off the $1/2(1,1,1)$ position is found to be

$$u = -0.0076 \quad \text{for} \quad e_{[111]} = 0.05,$$

$$u = -0.0049 \quad \text{for} \quad e_{[111]} = 0.025,$$

$$u = +0.0074 \quad \text{for} \quad e_{[111]} = -0.025$$

for the [111] strain and

$$u = -0.01205 \quad \text{for} \quad e_{[110]} = 0.05,$$

$$u = -0.00605 \quad \text{for} \quad e_{[110]} = 0.025,$$

$$u = +0.00600 \quad \text{for} \quad e_{[110]} = -0.025$$

for the [110] strain. The latter [110] set of data is quite consistent and leads to an internal-strain parameter of
\[ \zeta = 0.482(1). \]

It seems that there are appreciable nonlinear contributions to the internal strain only in the [111] case but not in the [110] case as is also found for the nonlinear contributions to the Pockels constant \( p_{44} \); but upon taking the average \( u \) for \( \varepsilon_{1[1]} = \pm 0.025 \) the next higher-order contributions should cancel, and the average value \( \zeta = 0.49(1) \) turns out to be very close to that from the [110] strain.

The computational result of Ref. 1 is \( \zeta = 0.45 \); with this value, \( p_{44} \) would have the wrong sign, and the authors of Ref. 1 treated \( \zeta \) as a fit parameter, reducing it appreciably in order to get close to their experimental data. A model calculation\(^{20}\) gives \( \zeta = 0.754 \).

2. \( \text{CaF}_2 \)

The findings for \( \text{CaF}_2 \) are qualitatively similar to those of \( \text{BaF}_2 \) with a quantitative difference resulting in

\[ \zeta = 0.321(1) \]

for the internal-strain parameter from the [110] strain in good agreement with \( \zeta = 0.29(1) \) of the [111] data set. The computational result of Ref. 1 is \( \zeta = 0.31 \). A model calculation\(^{20}\) gives \( \zeta = 0.432 \).

VI. SUMMARY

A. Linear Pockels constants

The experimental values for \( p_{11} \) and \( p_{12} \) exhibit a very large scatter, in particular for \( \text{CaF}_2 \), where values for \( p_{11} \) range from 0.026 to 0.056, see Table II. These values are derived from \( p_{11} + 2p_{12} (A_{1s}) \) and \( p_{11} - p_{12} (E_g) \), and naturally carry error bars as the sum of both of the latter. Results from optical experiments usually carry the dependence upon the radiation frequency\(^{1,21}\), and would need to be extrapolated to low frequencies if compared to our theoretical values; however, for energies much smaller than the gap energy, the optical constants vary only slowly.\(^{22}\)

From different model assumptions, calculations give the combined coefficient in the range \( 0.428 < p_{11} + 2p_{12} < 0.591 \) for \( \text{CaF}_2 \) and \( 0.542 < p_{11} + 2p_{12} < 0.71 \) for \( \text{BaF}_2 \). The results from other model calculations\(^{15,16,24}\) depend strongly on the particular models used and thus seem to be not very reliable in comparison with ab initio calculations; the problem seems to be the correct treatment of the change of the electronic polarizability of the model ions under strain.

Comparing the results for \( \text{BaF}_2 \) with those of \( \text{CaF}_2 \) one finds the largest differences in the values of \( p_{11} \) (next to those of \( p_{11} + 2p_{12} \)) in theory as well as in experiment. Both \( p_{11} \) and \( p_{12} \) are larger for \( \text{BaF}_2 \) than for \( \text{CaF}_2 \), and the shear constants \( p_{44} \) and \( p_{11} - p_{12} \) are smaller.

The deviation of our results for the Pockels constants from the experimental values are larger for \( \text{CaF}_2 \) than for \( \text{BaF}_2 \). The reason for the deviation cannot be found only in the use of the theoretical rather than the experimental equilibrium lattice constant; the theoretical lattice constants are smaller than either the low- or room-temperature values and disagree by 2% to 3%. For the experimental lattice constant the theoretical value of \( p_{11} + 2p_{12} \) becomes even smaller than the experimental one. (All Pockels constants or their combinations refer to the theoretical equilibrium volume.) We rather assume the differences to originate from the value of the dielectric constant, which is too large by about 15%\(^{5,6}\) (see also Table I) and which enters the Pockels constants quadratically. Also, as shown in Ref. 1 the use of a finer \( k \)-point mesh might bring the theoretical values closer to the experimental ones. Another deviation may come from using specific pseudopotentials and/or the LDA: with the presently used pseudopotentials and the LDA the results for the phonon properties have turned out to be quite satisfying.\(^{5,6}\)

Thus the unexpected theoretical sign of \( p_{11} \) for \( \text{CaF}_2 \) remains unexplained at the moment.

The error bars given in our tables are merely from numerical inaccuracies due to finite strains or different symmetries of strain. What is difficult if not impossible in an experiment can be done theoretically; choosing the strain strictly along a cube axis allows one to calculate \( p_{11} \) and \( p_{12} \) independently, and the results are in good agreement with our values derived from homogeneous and general uniaxial strain (along a cube axis).

The constant \( p_{44} \) is very sensitive to the internal strain, as the position of the \( F \) ions is not given by symmetry but by energy minimization. The theoretical value of \( p_{44} \) is overestimated by a factor of typically 2 when the internal strain is not taken into account.

B. Internal-strain parameter

Shear strain along the [111] or [110] direction makes the \( F \) atoms move off their symmetry positions. Using finite strain the shift depends nonlinearly on the strain. In the [110] case the nonlinear contribution to the internal-strain displacement is only of third order, thus making the [110] strain particularly insensitive to nonlinear effects. To our knowledge, the internal-strain parameter of \( \text{BaF}_2 \) and \( \text{CaF}_2 \) is not known experimentally.

C. Nonlinear Pockels constants

The results for the nonlinear Pockels constants are collected in Table III. As expected from the similarity of the linear strain coefficients of \( \text{CaF}_2 \) and \( \text{BaF}_2 \), also the nonlinear coefficients are of similar order of magnitude. The nonlinear coefficients are generally negative except \( p_{456} \). The strains are chosen in our calculations such that the strain tensors contain either only diagonal or only off-diagonal elements, and thus the nonlinear parameters \( p_{441} \) and \( p_{661} \) remain undetermined. To our knowledge, the nonlinear Pockels constants of \( \text{BaF}_2 \) and \( \text{CaF}_2 \) are not known experimentally.

The influence of the nonlinear terms on the calculation of the Pockels constants by taking differences rather than differentials have been found to be important in nearly all types of strain except [110]. Too small a strain might result in too high a numerical noise, and a calculation for too large a strain suffers from the nonlinearity; this has to be kept in mind in numerical treatments. To avoid this problem we extracted our data from nonlinear equations like (2) and (3).
This convention of the internal-strain parameter was originally introduced for the [111] strain in the diamond structure by J. Kleinman, Phys. Rev. 128, 2614 (1962). For \( \zeta=0 \) the F atoms remain in the center of the distorted tetrahedra, and for \( \zeta=1 \) the tetrahedral bond lengths are equal to the undistorted lengths to first order in the strain (pure bond bending). See also J. Sánchez-Dehesa, C. Tejedor, and J. A. Vergés, Phys. Rev. B 26, 5960 (1982).
