Abstract

The reliability of surface-based electrical resistivity tomography (ERT) for quantifying resistivities for shallow subsurface water processes is analysed. A method comprising numerical simulations of water movement in soil and forward-inverse modeling of ERT surveys for two synthetic data sets is presented. Resistivity contrast, e.g. by changing water content, is shown to have large influence on the resistivity quantification.

An ensemble and clustering approach is introduced in which ensembles of 50 different inversion models for one data set are created by randomly varying the parameters for a regularisation based inversion routine. The ensemble members are sorted into five clusters of similar models and the mean model for each cluster is computed. Distinguishing persisting features in the mean models from singular artifacts in individual tomograms can improve the interpretation of inversion results.

Especially in presence of large resistivity contrasts in high sensitivity areas, the quantification of resistivities can be unreliable. The ensemble approach shows that this is an inherent problem present for all models inverted with the regularisation based routine. The results also suggest that the combination of hydrological and electrical modeling might lead to better results.

1 Introduction

The quantification of water content by geophysical methods is an important focus of hydrogeophysical research. Surface based electrical resistivity tomography (ERT) is a promising method, because it is non-intrusive and can cover large surface areas quickly, while it might also be permanently installed for automated monitoring purposes. The development of inversion software for the processing of measured (apparent) resistivities to models of true resistivity has made fast and extensive surveys possible (Daily et al., 2004). Consequently, assessing the reliability of ERT for quantifying soil water content is a currently active research field.

ERT has successfully been used in a number of different applications, e.g. in borehole surveys of tracer experiments (Slater et al., 2000; Kemna et al., 2002) or in laboratory experiments (Binley et al., 1996; Slater et al., 2002). It has also been applied in surface-based surveys of the vadose zone (e.g. Daily and Ramirez, 1992) and of groundwater flow after heavy rain (Suzuki and Higashi, 2001).

Because choice of measurement configuration and inversion parameters may have significant influence on the survey results, improving the quality of ERT surveys has been an intense research topic. Dahlin and Zhou (2004) have com-

pared 10 different electrode arrays for 2D surveys and assessed their quality using synthetic data sets. Stummer et al. (2004) have developed algorithms to calculate optimal electrode arrays that provide as much information on the subsurface as possible. The effects of measurement errors (Zhou and Dahlin, 2003; Oldenborger et al., 2005) and geometry (Loke, 2000; Hennig et al., 2005; Sjoedahl et al., 2006) and inversion parameters (Carle et al., 1999; Rings et al., 2008) on the surveys have been studied.

Geophysical methods cannot directly determine hydrological properties like soil water content. They must be deducted using a general or calibrated relationship between the attribute of interest and the property available through geophysical measurements. In the case of ERT, the resistivities of the subsurface are related to water content by a generic petrophysical relation; usually the equation by Archie (1942). The resistivities, again, are not readily available from surface-based ERT surveys, but must be obtained from the measured apparent resistivities via inversion. The most widespread inversion methods rely on regularised least-squares minimisation to find the smoothest model of resistivities that gives a model response closest to the measured apparent resistivities.

Even assuming that the petrophysical relation between resistivity and water content is known, the resistivity models are non-unique and have likely been affected by the inversion process. The sensitivity of tomographic surveys plays a major role in the retrieval of subsurface characteristics, e.g. for surface-based ERT the sensitivity decreases with depth. Low sensitivity areas (but not only those) can often be plagued by inversion artifacts (e.g. Rings et al., 2008). The inversion process and the choice of inversion parameters, e.g. the regularisation parameters, determine how well the inverted model will reproduce the real distribution. However, some of the parameter choices can not reliably be

47 based upon observation, but must be fitted or depend on experience.
 48 Day-Lewis et al. (2004, 2005) refer to the loss of information caused by the
 49 inversion process, lack of sufficient prior information and survey geometry as
 50 'correlation loss'. They developed a method to compute the correlation loss as
 51 a function of the influencing factors. This allows an analytical integration of
 52 these factors into geostatistical analyses of quantitative hydrological field sur-
 53 veys, but needs a priori knowledge of covariance models. Singha and Gorelick
 54 (2006) suggest a nonstationary estimation approach that uses numerical simu-
 55 lations of transport and electrical current flow to deduct apparent petrophysi-
 56 cal relations. These methods modify the translation from the inverted models
 57 by adjusting the petrophysical relation but require either a priori knowledge
 58 or are computationally intensive.
 59 To assess the quality of ERT-based water content quantification, the complete
 60 processing chain including the inversion process, the petrophysical relation
 61 and numerical simulations of the soil water movement has to be evaluated.
 62 This study introduces a combined approach using soil hydraulic simulations
 63 and ensemble building of inverted models to estimate the uncertainty inherent
 64 in typical applications of ERT for water content quantification.

65 **2 Methods**

66 To evaluate the inversion process, a forward-inverse cycle approach is used. In
 67 numerous applications and studies, forward modeling of synthetic data sets
 68 has been used to gain additional insight and confidence into measurements
 69 and the inversion process (e.g. Loke and Dahlin, 2002; Godio and Naldi, 2003;
 70 Hauck and Vonder Muehll, 2003; Loke et al., 2003; Nguyen et al., 2005, 2007;

71 Rings et al., 2005). Forward modeling routines are applied to synthetic data
72 sets obtained from simulations of soil water movement. For two cases studies,
73 the approach is used to discuss how slight variations in the soil structure
74 influence the resistivity retrieval, and thereby the water content retrieval.
75 The second part of the study proposes an ensemble approach which allows an
76 overview of the possible range of inverted models, improves the analysis and
77 enables general assertions about how well a given model can be characterised
78 through the chosen inversion process.
79 In the following, each methodological step of the methods will be shortly
80 introduced, further discussion will illustrate how these steps can be applied to
81 create and analyse two synthetic data sets.
82 The forward-inverse cycle consists of three steps:

- 83 (1) *Simulation of water movement in soil*: A model with specific soil structure
84 is generated for numerical simulation of water movement. The movement
85 of a water front, caused by infiltrating rainfall, is simulated over time.
86 Characteristic states of water percolation are identified (starting with a
87 completely dry soil) and a simplified distribution of water content for
88 each state is extracted.
- 89 (2) *Generic resistivity model*: A generic resistivity model mirroring the soil
90 structure from (1) is created.
 - 91 • For a model representing a dry state (no water content), resistivities are
92 assigned based on typical values known from laboratory measurements
93 and/or literature.
 - 94 • For states of water percolation, changes in water content can be calcu-
95 lated using the water content distribution from (1). They can be trans-
96 ferred into resistivity changes by applying a petrophysical relation, e.g.

97 the equation by Archie (1942).

- 98 • A finite-element based forward modeling routine transfers the generic
99 resistivity models into model responses (sets of apparent resistivities)
100 that correspond to the data that would have been recorded by field
101 surveys. Random noise is added to simulate field measuring conditions.
- 102 (3) *Resistivity inversion*: The apparent resistivities are inverted using a suit-
103 able inversion scheme. The most widespread inversion schemes include
104 smoothness constrained (L2-norm) methods and robust (L1-norm) schemes
105 which are preferable if sharp layer boundaries are present. The forward-
106 inverse cycle is completed by comparing and evaluating the generic and
107 inverted model of resistivities.

108 The ensemble method comprises two steps:

- 109 (1) *Ensemble generation*: For each data set, an ensemble of 50 different in-
110 verted models is created by varying the inversion parameters and/or the
111 inversion scheme. The parameter set is chosen randomly from a parameter
112 space constrained to physically meaningful parameter sets.
- 113 (2) *Clustering*: A clustering algorithm is used to group similar models of the
114 ensemble. Cluster members can be averaged to simplify the analysis of
115 the ensemble.

116 2.1 Forward-inverse cycle

117 The application of this methodology was governed by the available software
118 codes for modeling and inversion. This section discusses how the steps were
119 specifically realised to create and analyse two synthetic data sets.

120 2.1.1 Simulation of water movement in soil

121 A numerical simulation of water movement was used to ensure that realistic
122 distributions of water content (and thus resistivity) were used in this study.

123 If a continuously connected air phase is assumed, the equation of motion for
124 water in soil was given by Richards (1931) as:

$$125 \quad \frac{\partial}{\partial t} \theta_w + \nabla \cdot [K_w(\nabla \Psi_m - \varrho_w \vec{g})] \quad (1)$$

126 with volumetric water content θ_w , hydraulic conductivity K_w , matric potential
127 Ψ_m , density of water ϱ_w and gravitational acceleration \vec{g} . To solve Eq. 1 for
128 water content, the material properties have to be given that connect θ_w , K_w
129 and Ψ_m . Usually, the soil-water characteristic $\theta_w(\Psi_m)$ and the conductivity
130 $K_w(\theta_w)$ are parameterised.

131 The most widely used parameterisation for the soil-water characteristics (van Genuchten,
132 1980), written in terms of water saturation $S = (\theta - \theta_r)/(\theta_s - \theta_r)$ with residual
133 water content θ_r , saturated volumetric water content θ_s and hydraulic head
134 $h_m = \Psi_m/(\varrho_w g)$, is

$$135 \quad S(h_m) = [1 + (\alpha h_m)^\nu]^{-1 + \frac{1}{\nu}} \quad (2)$$

136 with the scaling factor α , which is related to the air-entry value $1/\alpha$, and the
137 parameter ν connected to the pore size distribution. The hydraulic conduc-
138 tivity is characterised by applying the parameterisations of Mualem (1976). A
139 concise overview of the soil physics is given e.g. by Stephens (1996).

140 Equation 1 was solved numerically using the HYDRUS software (Simunek et al.,
141 2006). By defining time-variable precipitation and evaporation rates as atmo-
142 spheric boundary conditions, changes in the hydraulic head h_m and thus water

143 movement are induced.

144 The simulations were conducted with models representing a two-layered soil
145 representative of a site used in previous field studies (Rings et al., 2008). In
146 addition to an atmospheric boundary, a seepage boundary on the bottom al-
147 lowed water to leave the domain. From the simulations, characteristic states
148 of a water front infiltrating the domain were identified. Generally, beyond the
149 dry state, characteristic states should be chosen at times when the water con-
150 tent distribution has changed significantly, e.g. when one layer has become
151 completely saturated.

152

153 2.1.2 Generic resistivity model

154 The transfer from water saturation values S to electrical resistivity ρ is given
155 by the equations of Archie (1942). Here the quotient form is applied given by

$$156 \quad \frac{\rho_i}{\rho_j} = \left(\frac{S_j}{S_i} \right)^{-n} \quad (3)$$

157 where it is assumed that two measurements of the same soil at time steps i, j
158 differing only in water saturation are connected by the saturation exponent
159 n . n is near 2 for an organic overburden and in the range of 1.01 to 2.7 for
160 unconsolidated sands (Ulrich and Slater, 2004).

161 A generic model of resistivities was constructed calculate the response (mea-
162 surement data) an actual ERT survey would have retrieved. We simulated
163 field conditions by superimposing 3 % random noise on the resulting apparent
164 resistivity data set.

165 2.1.3 Inversion of apparent resistivities

166 The forward-inverse cycle is completed by inverting the simulated measure-
 167 ment data. Generic and inverted models can then be compared and the dis-
 168 crepancies analysed.

169 A robust inversion scheme by Loke et al. (2003), which is usually employed
 170 wherever sharp layer boundaries are expected, was chosen. It is implemented
 171 as an iteratively reweighted least-squares method (Wolke and Schwetlick, 1988)
 172 in the software RES2DINV:

$$173 \quad (\mathbf{J}_i^T \mathbf{R}_d \mathbf{J}_i + \lambda_i \mathbf{W}^T \mathbf{R}_m \mathbf{W}) \Delta \mathbf{m}_i = \mathbf{J}_i^T \mathbf{R}_d \Delta \mathbf{d}_i - \lambda_i \mathbf{W}^T \mathbf{R}_m \mathbf{W} \mathbf{m}_{i-1} \quad (4)$$

174 Here \mathbf{J}_i are Jacobian matrices of partial derivatives for the i -th iteration, \mathbf{W} is
 175 a roughness filter using a first-order finite-difference operator (deGroot Hedlin and Constable,
 176 1990), λ_i are damping factors, \mathbf{R}_d and \mathbf{R}_m are weighting matrices to give dif-
 177 ferent elements of data misfit and model roughness vectors equal weights,
 178 $\Delta \mathbf{m}_i$ is the change in model parameters for the i -th iteration and $\Delta \mathbf{d}_i$ is the
 179 data misfit vector containing the difference between calculated and observed
 180 apparent resistivities. Since the $\Delta \mathbf{d}$ values may extend over several orders of
 181 magnitude, logarithmic differences are employed.

182 Equation 4 is solved iteratively until either the root-mean square (RMS) of
 183 the data misfit vector $\Delta \mathbf{d}_i$ does not change significantly after an inversion
 184 step and/or it becomes smaller than the measurement accuracy. The weight-
 185 ing matrices \mathbf{R}_d and \mathbf{R}_m are predefined, and default values were chosen for
 186 λ_i .

187 2.2 Ensembles

188 Inversion problems for geoelectrical surveys are usually ill-posed, mixed deter-
189 mined problems. If the errors in data acquisition and in the inversion process
190 would be known quantitatively, the optimum model and its error distribution
191 could be determined exactly. Measurement errors often can only be estimated,
192 and further discrepancies may be introduced during inversion, especially if an
193 inversion code is used that does not rigorously optimise for a given error esti-
194 mate. Additionally, inverted models can be plagued by possibly large inversion
195 artifacts depending e.g. on resistivity contrasts.

196 2.2.1 Building Ensembles

197 Consequently, it might not be sufficient to analyse only the optimum model
198 (i.e. the model with the smallest data misfit), but to compute a range of
199 possible models addressing the inherent variability of the inversion process.
200 By randomly varying the inversion parameter set and creating an ensemble
201 of possible inversion models, the whole parameter space and thus the possible
202 model range is explored.

203 For the RES2DINV code used here, the selected parameters are listed in Table
204 1. The table also includes for each parameter the range from which a value was
205 automatically and randomly selected. The parameter selection encompasses
206 the use of smoothness constrained and robust inversions as well as two mixed
207 formulations with a robust constraint applied only on the data, and one with
208 a robust constraint applied only on the model. Further variations address
209 the regularisation, e.g. the damping factor, where an initial damping factor
210 λ_{start} and the maximum damping factor λ_{max} are varied. For most variations,

the maximum damping factor λ_{max} is kept at $\lambda_{max} = 10 \cdot \lambda_{start}$. Additional variations include the reduction of side block effects, the ratio of vertical to horizontal smoothness filtering and the use of the first iteration step model as a reference model for the further iterations instead of using the average of resistivities.

It should be noted that this choice of variations is specific for the software used in this study. However, the idea can easily be transferred to similar inversion approaches.

Almost all inversions resulted in inverted models with RMS errors smaller than 4% as can be expected from adding 3% artificial noise to the data set. Some single inversions, however, resulted in a larger RMS error. In section 3, both, inversion models with $\text{RMS} \leq 4\%$ and $> 4\%$, will be included to keep the ensembles balanced.

2.2.2 Clustering

Each ensemble is created as a set of 50 different inversion models and then regrouped using a k -means clustering algorithm (Dubes and Jain, 1988). 50 models have been chosen arbitrarily as a compromise between computational efficiency and the necessity to generate a sufficiently large ensemble for clustering. The k -means clustering method starts with a collection of *genes*; here a gene is a row of all block resistivities of one model. The distance d between two genes is calculated as a Pearson correlation

$$d = \frac{1}{N} \sum \left(\frac{x_i - \bar{x}}{\sigma_x} \right) \left(\frac{y_i - \bar{y}}{\sigma_y} \right) \quad (5)$$

where \bar{x} is the average of values in gene x and σ_x is the standard deviation of these values (Eisen et al., 1998). The k -means clustering starts with a user

235 decision on the number of clusters to be created, then randomly assigns each
236 gene to a cluster. For each cluster, the average model is created, then each gene
237 is assigned to the cluster it has the smallest distance from. These last steps
238 are repeated until an optimal solution is found. At least two runs creating
239 the same optimal solution are needed to reach a reliable solution (Eisen et al.,
240 1998). In this study, we used five clusters to generate a sufficiently large cluster
241 variability while ensuring that the number of ensemble members per cluster
242 is not too small.

243 *2.3 Applicability*

244 All five steps presented here form an analysis cycle for a synthetic case study
245 investigating the reliability of resistivity quantification for shallow subsurface
246 water processes. For application to field cases, it is possible to create and
247 analyse a simplified synthetic representation of the actual site following the
248 five steps above or apply only the ensemble and clustering steps to determine
249 the spread of possible inversion results.

250 **3 Synthetic case studies**

251 All test cases studied here are based on a simple two layer medium represent-
252 ing the structure of a full-scale dike model described in detail by Rings et al.
253 (2008). Although synthetic data sets are employed to distinctively focus on
254 specific anomalies, the material parameters were obtained from real observa-
255 tion. Hydraulic parameters, following the van Genuchten-Mualem parameter-
256 isation, were determined in a laboratory experiment by Scheuermann (2005).

257 For obtaining the parameters of the overburden, we used an inversion proce-
258 dure supported by the HYDRUS software. As no direct measurements of water
259 content in the overburden were available, a rainfall experiment described in
260 Scheuermann (2005) was simulated. Pressure head measurements in the sand,
261 but directly below the overburden, were used to invert the hydraulic param-
262 eters of the overburden. The resulting parameters are listed in Table 2 for
263 the two different materials. Meteorological data from the permanent station
264 Karlsruhe-Nordwest (Germany) were used as forcing. The Penman formula,
265 calibrated for grass cover by Doorenbos and Pruitt (1977), was applied to
266 these data to retrieve values for potential evapotranspiration. Combined with
267 measured precipitation rates, these values have been used as daily averages
268 for simulations of 210 days based on measurements in 2001.

269 Based on this two layer medium, two generic cases representing different ide-
270 alised case studies were created: The first case study simulates a defective
271 sealing, where an infiltration plume of water is generated in the sand layer. In
272 the second case study, a rectangular, hydraulically resistive anomaly is placed
273 in the sand underneath the organic overburden.

274 3.1 *First Case: Defective Sealing*

275 The first case is based on the idea of a crack in a dike sealing. Damaged
276 sealings are critical, as even through small cracks, large amounts of water can
277 infiltrate.

278 In this hypothetical case, water infiltrates through an otherwise sealed off
279 surface through one crack. The sealing is considered to be invisible to the
280 geoelectrical survey.

281 3.1.1 Water Simulation

282 In HYDRUS, the sealing is modeled as a no-flow boundary, and the crack
283 has an atmospheric boundary and is filled with sand material. The simula-
284 tion results show water infiltrating through the crack into the sand where it
285 diffuses into a sinking plume. The water content does not change outside of
286 the plume (Fig. 2). Three characteristic states of the simulated results can
287 be identified: dry state (Fig. 2a), infiltration state (the plume begins to form
288 in the sand, Fig. 2b) and the diffusion state (Fig. 2c), where the center of
289 the plume has propagated into the sand and the top layer is already drying.
290 The transfer from water content to resistivities was done by assuming a dry
291 state resistivity of $\rho = 400 \Omega m$ for the overburden and $\rho = 5000 \Omega m$ for the
292 sand and applying Eq. 3 with saturation exponent $n = 2$ for the overbur-
293 den and $n = 1.164$ for the sand (see Rings et al., 2008). During infiltration
294 and diffusion, this results in a minimal resistivity in the plume of $\rho = 2000 \Omega m$.

295

296 3.1.2 Forward-Inverse Cycle

297 Figure 3 shows three standard (robust) inversion models for the three states
298 of water percolation. A complete Wenner-Schlumberger array with electrode
299 separation 0.5 m has been simulated in the forward modeling. In the dry state,
300 the crack is clearly visible. In the infiltration state, the infiltrating plume is
301 characterised through a distinct lower resistivity than the background, while
302 in the diffusion state the inversion did not sufficiently resolve the shape of the
303 plume.

304 To analyse the dependence of the inversion results on the resistivity con-

305 trast between the plume and the host material, the plume resistivity was
 306 increased or lowered in steps of $250 \Omega m$ around the minimal plume resistivity
 307 of $2000 \Omega m$. A total of nine models with plume resistivity ranging from 1000
 308 to $3000 \Omega m$ were explored, while the background resistivity stayed constant
 309 at $5000 \Omega m$.

310 Generally, the resistivity of an anomaly ρ_{anom}^- is

$$311 \quad \rho_{anom}^- = \min\{\rho_i\} \quad (6)$$

312 for all model blocks i below the overburden. The misfit in the anomaly's
 313 resistivity $\Delta\rho_m$ is the difference between the resistivity of the anomaly in the
 314 generic $\rho_{anom,gen}^-$ and inverted model $\rho_{anom,inv}^-$:

$$315 \quad \Delta\rho_m = \rho_{anom,gen}^- - \rho_{anom,inv}^- \quad (7)$$

316 For this case study, ρ_{anom}^- corresponds to the resistivity in the center of the
 317 plume. Figure 4 shows the results of the forward-inverse cycle as $\Delta\rho_m$ vs the
 318 resistivity contrast. While the error in resistivity quantification is smallest
 319 for the original contrast of 4:10, smaller and higher contrasts both result in
 320 increasingly larger $\Delta\rho_m$.

321 $\Delta\rho_m$ is slightly smaller in the infiltration state. In the diffusion state, the
 322 center of the plume has sunk to greater depth, where the reduced sensitivity
 323 of ERT may be the reason for a less accurate quantification.

324 3.1.3 Ensemble

325 The inversion ensemble for the case of the defective sealing and the diffusion
 326 state is shown in Figure 5. All models within the ensemble detected the over-

327 burden with the damaged sealing, but the model parts below this overburden
 328 show different features. In the first cluster, Ω -sloped artifacts appear to the
 329 side of the plume with equal resistivity as the plume itself. In the second
 330 cluster the artifacts appear as well, but have comparably higher resistivity, so
 331 that the plume appears as a distinct feature. In the third cluster, both plume
 332 and Ω -sloped artifacts are roughly in the same resistivity range, but have
 333 a higher resistivity than in cluster 1. The fourth cluster comprises strongly
 334 damped models where the plume is mostly visible. The last cluster shows
 335 models where the plume is clearly visible, with comparably better contrast,
 336 but mostly the vertical extent of the plume feature is overestimated.

337 To comprehend the ensemble results in a simple way, averaged models of each
 338 cluster are shown in Figure 6. As the clustering process already involves av-
 339 eraging, this is a valid method. In Figure 6, the mean models for each of
 340 the clusters of the ensemble shown in Figure 5 are now listed according to
 341 the number of cluster members. It must be noted that the smallest cluster
 342 contains only 3 models, whereas the largest cluster contains almost half the
 343 models of the ensemble. The average RMS error of each cluster is below 4%.

344 The most prominent feature retrieved in all models is the two-layered struc-
 345 ture, which can be observed in all five clusters. This structure is present even
 346 in clusters where the damping is strong enough to nearly hide the plume
 347 anomaly. When comparing clusters 3-5 to the strongly damped inversion re-
 348 sults in cluster 1, the typical Ω -sloped structure can be identified as an artifact
 349 at the lateral boundaries of the plume. Compared to the standard model (0),
 350 the cluster averages allow a much better identification of features, even though
 351 some interpretational experience or a priori knowledge is needed to distinguish
 352 between real anomalies (cluster 5) and artifacts (cluster 4).

353 3.2 Second Case: Hydraulically Resistive Anomaly

354 In the second case, the accuracy of resistivity quantification for a rectangular,
355 hydraulically resistive anomaly placed below the organic overburden is stud-
356 ied. First, a soil model with an organic overburden and an anomaly at 0.55
357 m depth was created in HYDRUS. To represent the hydraulically resistive
358 material of the anomaly, the same material as for the organic overburden was
359 used. Then, multiple versions of this model were created with slightly differ-
360 ent geometries. Table 3 shows the differences between the respective models,
361 which will be explained in the following.

363 3.2.1 Water Simulation

364 In the simulation of water movement, a dry state, an infiltration state and a
365 diffusion state were identified as characteristic states of an infiltrating water
366 front. In the dry state (Fig. 7a), the soil is completely free of water. In the
367 infiltration state (Fig. 7b), the water front is propagating into the volume. The
368 hydraulically resistive anomaly causes water to impound on top, only slowly
369 infiltrating into the anomaly. In the diffusion state (Fig. 7c), the infiltration
370 front has reached the bottom boundary of the model, and the organic overbur-
371 den and parts of the sand directly below are beginning to dry. The anomaly
372 is filled with water that infiltrates into the sand beneath.

373 Analysis of the quality of water content estimation through ERT was con-
374 ducted for a variety of models and electrode configurations based on the three
375 states of water percolation in Figure 7. To study the influence of contrasting
376 resistivities at the surface, models with and without an organic overburden

377 were used for simulation. In addition, the depth of the anomaly was varied in
 378 steps of 0.2 m with the upper boundary at 0.35 m to 1.15 m depth. To examine
 379 the effect of electrode configuration, two different electrode arrays (complete
 380 Wenner-Schlumberger and Dipole-Dipole arrays) with an electrode spacing of
 381 0.5 m were used for each model (Table 3).

382

383 3.2.2 *Forward-Inverse Cycle*

384 Inspection of the inverted models (Fig. 8, right column) shows that the rectan-
 385 gular shape of the anomaly cannot be exactly retrieved. Determination of an
 386 average resistivity of the anomaly would be dependent on an arbitrary deter-
 387 mination of anomaly borders. It is also not possible to determine the average
 388 resistivity at the actual position of the anomaly, since the perceived depth of
 389 the anomaly is greater than the actual depth.

390 In the following, results for the different models shown in Table 3 will be
 391 compared regarding $\Delta\rho_m$ (Eq. 7), which now corresponds to the (minimal) re-
 392 sistivity of the anomaly. Figure 9 shows $\Delta\rho_m$ as a function of anomaly depth.
 393 For the Wenner-Schlumberger array, $\Delta\rho_m$ increases with anomaly depth, reach-
 394 ing up to 2-3 times the expected value. A much better estimate is obtained if
 395 no organic overburden is present (gray curves). For these cases, better quan-
 396 tifications of ρ_{anom}^- are possible and $\Delta\rho_m$ increases only slightly with depth. In
 397 the diffusion state, significantly smaller errors occur compared to other states
 398 of water percolation, especially in the presence of an organic overburden.
 399 As can be seen in Figure 8, the error in depth resolution is rather large. If
 400 an organic overburden is present, the thickness of this layer is overestimated,
 401 causing a shift in the vertical position of the anomaly of 0.3 to 0.4 m. It was

also observed that at greater depths, the position stays approximately the same for an anomaly expected at 0.75 m to 1.15 m depth. Again, in the case of a model without an organic overburden, the higher sensitivity due to higher resistivities near the surface makes better depth determination possible. For models simulated with the Dipole-Dipole array, errors for models with organic overburden are significantly smaller than for the Wenner-Schlumberger array. However, the Dipole-Dipole array was shown to be very sensitive to noise and disturbances at the surface (like a stone pathway), to a point where measurements taken using this array could not be interpreted with the available inversion routines. As a measure of the quality of the inversion, a simple criterion containing the model misfit M as the sum of all errors has been applied:

$$M = \sum_{F_i} |\rho_{inv,i} - \rho_{gen,i}| \quad (8)$$

where F_i is the i -th model block of the inversion domain discretisation. Comparison of M for the different states of water percolation (Fig. 10) shows that the diffusion state gives significantly better results. In this state, the misfit below the organic overburden and to the sides of the anomaly is much smaller, additionally the depth of the anomaly and overburden are better resolved. Figure 11 shows the spatial error distribution for each state. In the dry state, the biggest errors stem from an overestimated thickness of the overburden, which also entails further mispositioning of the anomaly. The anomaly itself is also vertically elongated, leading to considerable errors in the lower parts. In the diffusion state (Fig. 11 (b)), the resistivity contrast between overburden and wet sand is much smaller, due to a) the sand having a reduced resistivity as it is more saturated with water and b) the overburden being dryer as in

the previous states, resulting in a higher resistivity. As a consequence of this reduced resistivity contrast, the errors resulting from an incorrect overburden thickness are reduced as well.

3.2.3 Ensemble

For the case of the hydraulically resistive anomaly, the random set of parameters is applied to generic models of all three different states of water percolation. To assure comparability, the random parameter set stays the same for each of the three models.

A model with an anomaly at 0.75 m depth was used, including an organic overburden and using the Wenner-Schlumberger array. For each state, an ensemble of 50 inverted models was created. For simplification, only mean cluster members are shown. Figure 12 shows the five clusters per ensemble with the respective number of ensemble members. The respective $\Delta\rho_m$ is listed in Table 4.

- Dry State: The rectangular shape of the anomaly is retrieved variably well, but for the models 4 and 5, where the thickness of the anomaly is smaller, a strong overestimation of resistivities is present in the lower part of the model ($> 7000 \Omega m$ instead of $5000 \Omega m$). The resistivity of the anomaly ρ_{anom}^- is much too high for all five models. For models 1 and 2 that contain most of the ensemble members, the anomaly is vertically elongated.
- Infiltration State: In four models, the shape of the anomaly has been retrieved quite well, but for model 10, two zones of minimal resistivity have been detected rather than the rectangular shape. In all models, $\Delta\rho_m$ is very

large compared to the expected resistivity of the anomaly $\rho = 65 \Omega m$. Again, models 9 and 10 (same inversion parameters as model 4 and 5) overestimate the background resistivity at greater depth.

- Diffusion State: The resistivity of the anomaly is detected with lower resistivity as in the infiltration state, closer to the expected resistivity of $45 \Omega m$. Again, in model 13 and 15, the strong inversion artifact is present near the bottom coinciding with the shape of the anomaly being retrieved quite well. These artifacts are not present in model 11, 12 and 14, where the anomaly is vertically elongated. Model 15 presents a mixed case of a slightly elongated anomaly and an artifact of smaller extent than in model 13.

Table 4 shows, sorted for the cluster representatives, the misfits in the anomaly's resistivity. While it is apparent that the errors are large in each case, they are again considerably smaller for the diffusion state.

4 Discussion and Conclusion

The ability of electrical resistivity tomography to accurately determine resistivity distributions was examined. A two-step model approach was used to create synthetic data sets. It comprises the modeling of soil water movement for synthetic soil data sets and a transfer into a model of generic resistivities using a petrophysical relation. A forward-inverse cycle is used evaluate how well the geophysical inversion scheme can reconstruct the given soil data set and its water content. An ensemble and clustering approach is proposed because a single model deduced as the optimal model does not necessarily reproduce the expected resistivities accurately.

The methods were applied to two case studies of simple soil models based on a

two-layered structure reproducing field observations. The first case simulates the infiltration of water through a cracked surficial sealing, and the second a hydraulically resistive anomaly in a sand layer.

Key results of the forward-inverse modeling in this study include:

- In the presence of large resistivity contrasts, e.g. a conductive organic overburden, the retrieval of accurate resistivity values beneath this layer using the regularisation based inversion method applied in this study is not possible. However, if the volume is monitored at various stages of water percolation, the retrieval quality can differ. Especially in the diffusion state, much better accuracy was possible.
- The model misfit increases with depth, as the sensitivity of the inversion model to the data decreases.
- In the absence of an organic overburden, a much better quantification is possible because of a lower resistivity contrast.
- The numerical study showed that a Dipole-Dipole array provides more accurate inversions than the Wenner-Schlumberger array. However, in practical applications, it has to be ensured that the signal-to-noise ratio is sufficiently large.

As a consequence, an ensemble approach was introduced that creates multiple inversion models for one data set by randomly choosing the inversion parameters from the possible (and numerically plausible) parameter space. By using clustering methods, averaged models representing different clusters in the ensemble can be created and compared. Key results of the ensemble approach include:

- 500 • Clustering of ensemble members allows an evaluation of the different possi-
 501 ble models that fit the data. Areas likely to be plagued by artifacts can be
 502 identified and the reliability of standard inverted models can be evaluated.
- 503 • However, the quantification of resistivities is not considerably improved by
 504 ensembles. For example, it became apparent that resistivities retrieved with
 505 smaller misfits in one region can coincide with larger artifacts in other re-
 506 gions.
- 507 • The clustering of ensembles allows an overview of the ensemble, without
 508 losing information about the ensemble.

509 The ideas of the approaches presented here can easily be adapted to different
 510 models and inversion methods. For the specific inversion process with regular-
 511 isation used in this study, it can be concluded that a reliable quantification of
 512 resistivity values is not possible. The use of additional information, e.g. within
 513 a framework aiming at directly inverting or calculating hydrological proper-
 514 ties from collected data sets that not only contain resistivity measurements,
 515 but also data about the flow conditions, e.g. meteorological data, should be
 516 considered.
