## Abstract

Orange Carotenoid Proteins (OCPs) are photoswitchable macromolecules playing an important role in non-photochemical quenching of excess energy in cyanobacterial light-harvesting. Upon absorption of a blue photon (450-500 nm) OCPs undergo a structural change from the ground state  $OCP^O$  to the active state  $OCP^R$ , but high-resolution structures of the active state  $OCP^R$  are not yet available. Here we use small-angle scattering methods combined with simulation tools to determine low-resolution structures of the active state at low protein concentrations via two approaches: first, directly by in-situ illumination of wild-type OCP achieving a turnover to the active state of >90%, and second, by using the mutant  $OCP^{W288A}$  anticipated to mimic the active state structure. Data fits assuming the shape of an ellipsoid yield three ellipsoidal radii of about 9, 29 and  $51 \pm 1$  Å, respectively, in the case of the ground state  $OCP^O$ . In the active state, however, the molecule becomes somewhat narrower with the two smaller radii being 9 and only  $19 \pm 3$  Å, respectively, while the third dimension of the ellipsoid is significantly elongated to  $85 - 92 \pm 5$  Å. Reconstitutions of the active state structure corroborate that  $OCP^R$  is significantly elongated compared to the ground state  $OCP^O$  and characterized by a separation of the N-terminal and C-terminal domains with unfolded N-terminal extension. By direct comparison of small-angle scattering data, we directly show that the mutant  $OCP^{W288A}$  can be used as a structural analogue of the active state  $OCP^R$ . The small-angle experiments are repeated for  $OCP^O$  and the mutant  $OCP^{W288A}$  at high protein concentrations of 50-65 mg/ml required for neutron spectroscopy investigating the molecular dynamics of OCP (see accompanying paper). The results reveal that the  $OCP^O$  and  $OCP^{W288A}$  samples for dynamics experiments are preferentially dimeric and widely resemble the structures of the ground and active states of OCP, respectively. This enables us to properly characterize the molecular dynamics of both states of OCP in the accompanying paper.

## 1. Introduction

Many cyanobacteria employ Orange Carotenoid Proteins (OCPs) for the purpose of protecting their sensitive photosystems against the harmful effects of excess light energy in a process termed non-photochemical quenching (NPQ) of phycobilisome (PBS) antenna fluorescence<sup>1</sup>. OCPs are light-triggered photoswitches employing ketocarotenoids as cofactors, which undergo photoconversion from the basal, dark-adapted orange state (OCP<sup>O</sup>) to the active red state (OCP<sup>R</sup>) upon absorption of a blue photon (450-500 nm)<sup>2-5</sup>. OCP<sup>R</sup> is able to interact with phycobilisome antenna complexes to consequently quench their fluorescence, thereby preventing photodamage of the underlying photosystems by dissipating excessively absorbed light energy into heat<sup>6</sup>. Structurally, the about 35 kDa water-soluble OCPs are subdivided into two domains of about equal size, an N-terminal and a C-terminal domain (NTD and CTD, respectively), which almost symmetrically encapsulate a single xanthophyll molecule in a common central cavity<sup>7,8</sup>. The predominant xanthophyll is 3'-hydroxy-echinenone when purified from native cyanobacteria (e.g. *Synechocystis* sp. PCC 6803 or *Arthrospira maxima*), but photoactivity is also preserved with only 4(4')-ketolated xanthophylls (either echinenone, carrying a single keto group in 4-position of the terminal ring, or the 4,4'-diketolated canthaxanthin, when expressed in appropriate *E. coli* strains), whereas insertion of  $\beta$ -carotene or (3,3'-hydroxylated) zeaxanthin results in non-photoconvertible protein<sup>9</sup>. While the OCP<sup>O</sup>→OCP<sup>R</sup> conversion is triggered by photon absorption<sup>5</sup> (albeit with very low quantum yield of ~0.2 %<sup>10,11</sup> making OCP an excellent light intensity sensor over the range of ambient light intensity fluctuations), the back-conversion occurs spontaneously (thermally) even in the dark, since the OCP<sup>O</sup> state is the thermodynamically stable one. In cyanobacteria, the OCP-related NPQ is terminated by the about 16 kDa Fluorescence Recovery Protein (FRP)<sup>12-15</sup>, which exerts a dual action by speeding up detachment of the quenching-active OCP<sup>R</sup> from the PBS and accelerating the OCP<sup>R</sup>→OCP<sup>O</sup> back-conversion, the latter by mainly increasing the pre-exponential factor in the Arrhenius formulation of the temperature-dependent rate constant while leaving the activation energy of the process almost unchanged<sup>16</sup>.

**Figure 1:** OCP<sup>0</sup> monomer according to the crystal structure of Leverenz et al. (pdb-code 4XB5)<sup>17</sup>: the N-terminal domain is shown in green, the C-terminal domain in orange, the N-terminal extension in blue and the carotenoid in cyan. The four protein residues interacting with the carotenoid are highlighted in purple color, see text.

In the basal OCP<sup>0</sup> state, the protein adopts a compact structure (see Fig. 1), which has been known in atomic detail for many years<sup>7, 17, 18</sup>. While the NTD is mainly composed of  $\alpha$ -helices as major structural elements, the CTD is of mixed  $\alpha$ -helical/ $\beta$ -sheet character and belongs to the wide-spread family of nuclear transport factor 2 (NTF-2)-like proteins (PFAM 02136). The OCP<sup>0</sup> structure is stabilized by multiple protein-protein interactions across the NTD-CTD interface, by the NTD-CTD linker, and by the N-terminal extension (NTE) of the NTD encompassing the  $\alpha$ A helix that attaches to a specific site on the  $\beta$ -sheet surface of the CTD<sup>19, 20</sup>. The only specific interactions between the carotenoid and the protein are two H-bonds between the 4-keto oxygen of the carotenoid and the hydroxyl group of Tyr-201 as well as to the imino nitrogen of Trp-288 in the CTD (amino acid numbering according to *Synechocystis sp.* PCC 6803)<sup>21, 22</sup>. These amino acids

1  
2  
3 are highly conserved in all known OCP sequences, and mutations at either of the two positions  
4 interfere drastically with the ability to photoswitch, with carotenoid preference, with spectroscopic  
5 characteristics, or with other important physico-chemical properties of the protein. Within the  
6 NTD, Tyr-41 and Trp-110 are also in interaction distance to the other terminal ring of the  
7 carotenoid and involved in e.g.  $\pi$ -stacking, but mutations in these positions mostly have less severe  
8 consequences<sup>18</sup>. Results of a recent study employing dynamic X-ray crystallography on full-length  
9 OCP suggest that the aforementioned H-bonds are the first to break upon photoactivation. This  
10 triggers a whole series of events that eventually result in the formation of the OCP<sup>R</sup> state<sup>10, 23, 24</sup>.  
11 The latter is characterized by complete separation of the domains, detachment of the NTE from the  
12 CTD, and translocation of the carotenoid into the NTD<sup>8, 17, 25</sup>. These studies already indicate that  
13 the scheme OCP<sup>O</sup>↔OCP<sup>R</sup> for the “photocycle” of OCP is an oversimplification<sup>10</sup>. Already in  
14 2008, Wilson et al.<sup>5</sup> revealed by fs absorption spectroscopy that after decay of the excited hECN  
15 states on a ps timescale, a photoproduct remains at very low amplitude which is slightly red shifted  
16 as compared to the absorption of OCP indicating that these states of the chromophore may be  
17 similar but not identical to the state in OCP<sup>R</sup> and that subsequent relaxation of the protein takes  
18 place on timescales longer than nanoseconds. A recent multi-parametric spectroscopy study has  
19 shown that several spectroscopically discernible intermediates exist on the way, and that there is  
20 considerable asynchrony between the spectroscopic state of the carotenoid cofactor and the  
21 structural organization of the surrounding protein<sup>24</sup>. Thus, on the timescale of picoseconds  
22 immediately following photoexcitation<sup>5</sup>, characteristics of the spectrally red-shifted intermediate  
23 are already observed, which is long before the large conformational changes leading to the  
24 extended configuration of the OCP<sup>R</sup> state with separated domains. On the contrary, during back-  
25 reversion, there are already spectral characteristics for some orange state, before the final structural  
26 reorganization to form the compact, dark-adapted OCP<sup>O</sup> structure comes to completion<sup>10</sup>.  
27  
28 Unfortunately, a high-resolution structure of the OCP<sup>R</sup> state is still elusive, although such  
29 information would be mandatory to understand the principles of photoprotective action of the OCP  
30 protein and of its color tuning. The process of photoconversion and formation of the OCP<sup>R</sup> state  
31 eventually leads to (i) complete separation of the domains, which are only connected via the

2  
3 flexible NTD-CTD linker, (ii) a large increase of the hydrodynamic volume of the protein, creating  
4 properties of a molten globule state with enhanced conformational flexibility<sup>11</sup>, and (iii) full  
5 translocation of the carotenoid cofactor by 12 Å into the NTD<sup>17</sup>. Such extensive carotenoid  
6 repositioning has first been hypothesized based on the elucidation of the X-ray crystal structure of  
7 the NTD of OCP, which has previously been observed as a carotenoid-containing spontaneous  
8 hydrolysis product in native OCP preparations and was termed Red Carotenoid Protein according  
9 to its color appearance. A recent FRET triangulation study showed that this carotenoid  
10 translocation indeed occurs dynamically in the full-length OCP protein<sup>26</sup>. Besides the considerable  
11 disorder, the metastability of the OCP<sup>R</sup> state is problematic for high-resolution structural studies,  
12 since the protein would have to be permanently illuminated with intense blue light. However,  
13 sequence variants are already at hand, which mimic the properties of the red signaling state of OCP.  
14 One of these variants is the OCP-W288A mutant protein (initially termed “OCP<sup>W288A</sup>” or “purple  
15 carotenoid protein”), which has been shown to have very similar hydrodynamic properties like the  
16 OCP<sup>R</sup> state, to interact with FRP and to be capable of phycobilisome fluorescence quenching  
17 without requiring photoactivation, and, therefore, should be an ideal model for the structure of the  
18 OCP<sup>R</sup> signaling state<sup>15</sup>.

19  
20 In this regard, small-angle neutron and X-ray scattering (SANS and SAXS, respectively) are  
21 valuable experimental techniques providing structural information in aqueous solution, i.e. under  
22 the same conditions as applied in spectroscopic experiments (for reviews, see<sup>27,28</sup>), while neutron  
23 spectroscopy probes the molecular dynamics of biomolecules<sup>29-31</sup>, see accompanying paper. SANS  
24 and SAXS are especially powerful in investigations in the case of complex formation out of  
25 proteins with known crystal structures<sup>32,33</sup> as well as in the determination of intrinsically  
26 disordered structures like detergent micelles or belts of solubilized membrane proteins<sup>34,35</sup>. Further  
27 applications in photosynthesis research (for a review see<sup>36</sup>) encompass neutron studies of the  
28 organization of plant thylakoid membranes in solution<sup>37,38</sup>, of the hydration dependence of the  
29 PS II membrane spacing<sup>39</sup>, the structural arrangement of cyanobacterial thylakoid membranes<sup>40</sup>,

2  
3 In the present study, we apply SANS and SAXS for investigations of the structure of the active  
4 state OCP<sup>R</sup> using two different approaches: first, via illumination of wild-type OCP, and second,  
5 employing the mutant OCP<sup>W288A</sup>, which is expected to widely resemble the structure of OCP<sup>R</sup> see  
6 above. The results confirm that OCP undergoes a domain separation along with a considerable  
7 elongation upon illumination. Moreover, the solution structure of the mutant OCP<sup>W288A</sup> is shown  
8 to have a highly similar structure as OCP<sup>R</sup> in aqueous solution. Comparative neutron spectroscopy  
9 studies characterizing the molecular flexibility of OCP and of the molten globule state of OCP<sup>W288A</sup>  
10 on the picosecond to nanosecond timescales are reported in the accompanying paper. In the present  
11 paper, we verify that both OCP and OCP<sup>W288A</sup> retain their solution structures even at the relatively  
12 high protein concentrations of 50 – 65 mg/ml required for neutron spectroscopy.

## 2. Materials and Methods

**Sample Preparation: *cDNA constructs and cloning:*** For the expression of OCP and the pink species of the OCP-W288A mutant (PCP) we used a plasmid harboring the DNA sequence of OCP according to the published amino acid sequence (Pubmed/UniProt entry P74102) which was optimized for codon usage in *E.coli* by artificial gene synthesis (GeneOptimizer® algorithm, GeneArt, Life Technologies). The OCP-DNA was cloned into the first multiple cloning site of the pRSFDuet-1 vector (Novagen) by excision with BamHI and NotI. The resulting N-terminal amino acid sequence was: MGSSHHHHHSQDPATM(1)..., which was verified by DNA sequencing (Eurofins MWG Operon, Germany). The OCP wild type protein was cloned into a modified pRSFDuet-1 vector which encodes a specific human rhinovirus 3C protease cleavage site (LEVLFQ/GP) for cleaving the His6-tag (plasmid called “pRSFDuetM”). After incubation with 3C protease the N-terminal amino acid sequence for the OCP-WT was: GPDPATM(1)... . The W288A mutant was generated by using the QuikChange® site-directed mutagenesis kit (Stratagene) according to manufacturer’s instructions.

***Protein expression and purification:*** For expression of the holo-protein the pRSFDuetM-OCP or pRSFDuet-PCP plasmid was transformed in echinenone producing BL21(DE3) *E.coli* cells (New England Biolabs). The carotenoid expression is essentially described in <sup>22</sup>. The expression conditions were the same for all constructs: 500 ml of medium supplemented with 34 µg/ml chloramphenicol (carotenoid producing plasmid) and 50 µg/ml kanamycin (for OCP plasmid) were inoculated from an overnight culture to an OD of 0.05 and grown in an orbital shaker at 37 °C and 220 rpm until the OD reached 0.7-0.8. After the induction with 0.5 mM IPTG the cells were grown for 48-72 h at 25 °C. Cells were harvested by centrifugation at 10,000 × g at 4 °C for 20 minutes and frozen until use.

The frozen cell pellets were resuspended in phosphate buffer (137 mM NaCl, 2.7 mM KCL, 12 mM phosphate, pH 7.4) and supplemented with 100 mg lysozyme and protease inhibitors (Complete®, Roche). The cell lysis was performed by 3-4 freeze/thaw cycles on dry ice with absolute ethanol and a water bath at room temperature. After removal of the cell debris by centrifugation (18,000 × g, 4 °C) the clarified supernatant was purified by affinity chromatography

1  
2  
3 with a peristaltic pump using 5 ml Co<sup>2+</sup>-HiTrap Talon crude columns (GE Healthcare). The protein  
4 was eluted by an imidazole containing phosphate buffer (250 mM imidazole). After affinity  
5 chromatography either the His<sub>6</sub>-tag cleavage or a hydrophobic-interaction-chromatography was  
6 performed. For cleavage with 3C protease the purified 3C protease was added in a 1:1000 dilution  
7 (referred to the total protein mass) to the eluted protein solution and incubated for 18 h at 4 °C in  
8 3C protease buffer (20 mM Tris, 100 mM NaCl, 2 mM DTT, pH 7.5). After His<sub>6</sub>-cleavage the  
9 protein solution was applied to an affinity chromatography column for the second time and the  
10 flow through was collected for dialysis in HIC buffer (500 mM (NH<sub>4</sub>)<sub>2</sub>SO<sub>4</sub>, 100 mM NaCl, 10 mM  
11 phosphate, pH 7.4) over night at 4 °C. The hydrophobic-interaction-chromatography was carried  
12 out on a HiPrep 16/10 Phenyl HP column (Ge Healthcare) with an ÄKTA FPLC purification  
13 system (GE Healthcare). The protein was eluted using a buffer gradient with a second buffer which  
14 contained 10 mM phosphate and 100 mM NaCl. After HIC the protein was dialyzed in phosphate  
15 buffer and finally a size-exclusion-chromatography was performed on a Superdex™ 200 Increase  
16 10/300 column (GE Healthcare). The large amount of protein that is necessary for QENS  
17 experiments was produced by using a rich minimal medium<sup>43</sup>. Finally, about 6 liters of MTM was  
18 used to obtain a total of 100 mg protein for QENS experiments.

34  
35 *Protein preparation for QENS and SANS experiments:* The buffer was exchanged from H<sub>2</sub>O to  
36 D<sub>2</sub>O in order to suppress the solvent scattering in the case of QENS experiments and to decrease  
37 the incoherent background in the case of SANS experiments. This was achieved by using a  
38 phosphate buffer in D<sub>2</sub>O prepared by dissolving a PBS tablet (Life technologies) in 100 ml D<sub>2</sub>O  
39 (Sigma Aldrich, 99.9% D content). The purified proteins were concentrated in a centrifugation  
40 concentration filter (PALL corporation Macrosep®) to 400-500 µl and diluted with D<sub>2</sub>O phosphate  
41 buffer for 3-4 times till a D<sub>2</sub>O content of 99.9% was reached. The protein solutions were sealed in  
42 small tubes and frozen at -80 °C until use.

50  
51  
52 **Small-Angle Neutron and X-ray Scattering:** The SANS experiments on OCP and OCP<sup>W288A</sup>  
53 samples were carried out at the KWS-1 small-angle diffractometer (JCNS at MLZ, Garching,  
54 Germany). KWS-1 is perfectly suited to perform high-resolution measurements thanks to its 10%  
55  
56  
57  
58

wavelength spread. The neutron wavelength used in the present experiment was 5 Å. By measuring at two sample-detector distances of 8 m and 20 m, we could cover the Q range from 0.006 to 0.45 Å<sup>-1</sup>. The samples were kept in standard 1 mm Helma cells at a constant temperature of 15 °C. We used samples in the 100% D<sub>2</sub>O contrast at two concentrations of about 64 mg/ml and 1 mg/ml, respectively. The data reduction procedure includes the correction according to detector sensitivity mask. The data treatment is carried out using the QtiKWS program<sup>44</sup>. More details about the KWS-1 can be found in<sup>45</sup>.

The SAXS measurements were performed on the diffractometer SmartLab™ (Rigaku) at the Institute of Physics, University of Tartu by using the SAXS optics and CuKα radiation (λ=1.56098 Å, rotating anode X-ray tube working at 180 mA and 45 kV, sample-detector distance of 300 mm). The program NanoSolver (Rigaku) was used to pre-process the scattering data, to subtract the buffer scattering (see sample preparation) and to correct slit smearing effects.

### SANS/SAXS data analysis

The small-angle scattering from a diluted solution of monodisperse particles follows the master equation<sup>27, 28</sup>

$$\frac{d\sigma(q)}{d\Omega(q)} = n\Delta\rho^2V^2P(q)S(q), \quad (1)$$

where n is the number of particles, Δρ is the difference in scattering length densities between the particles and the solvent, and V is the specific volume of the particle. P(q) is the form factor, which is a function of the averaged shape and the averaged size of the scattering particles. The effective structure factor is presented in the formula as S(q), which is equal to unity for diluted solutions without interaction between the individual particles.

The pair correlation function  $P(R)$  and particle maximum dimension  $D_{\max}$  were determined by fitting the data using the indirect Fourier transform (IFT) method as implemented in the program GNOM<sup>46</sup>.

In case of partial aggregation, the SANS data were fitted using a linear superposition of two intensity profiles: a) the scattering profile of an ellipsoid with uniform scattering length density corresponding to the OCP proteins, and b) a power law

$$I(q) = Aq^x \quad (2)$$

representing the scattering from aggregates.

The scattering profile of an ellipsoid with the radii of its three axes being  $a$ ,  $b$ , and  $c$  (assuming  $a \leq b \leq c$ ) and with a uniform scattering length density is given by the equation<sup>47</sup>

$$I(q) = \frac{scale}{V_{el}} \int_0^1 \int_0^1 \phi^2 \left\{ q \left[ a^2 \cos^2\left(\frac{\pi x}{2}\right) + b \sin^2\left(\frac{\pi x}{2}\right)(1 - y^2) + c^2 y^2 \right]^{\frac{1}{2}} \right\} dx dy, \quad (3)$$

where

$$\phi^2(x) = 9 \left( \frac{\sin(x) - x \cos(x)}{x^3} \right)^2 \quad (4)$$

and

$$V_{el} = \frac{4\pi}{3} abc. \quad (5)$$

The global fitting of SANS curves was performed using the SANS software developed at NCNR (NIST)<sup>48</sup>.

1  
2 Low-resolution solution structures were obtained using the ATSAS reconstitution tool DAMMIN  
3  
4 developed by the Svergun group based on a reverse Monte Carlo minimization approach <sup>49, 50</sup>. The  
5  
6 structural models derived within this study were generally averaged over 20 iterations.  
7

8  
9 SAXS data were also analyzed using the software package CORAL (COMplexes with RANdom  
10  
11 Loops), which allows to define flexible portions in a known crystal structure, while the remaining  
12  
13 part of the molecule is modeled as a rigid body <sup>51</sup>. In our analysis, NTD (residues 19-163) and CTD  
14  
15 of OCP (residues 171-311) were predefined as rigid bodies based on the 3MG1 pdb code of the  
16  
17 OCP<sup>O</sup> dimer <sup>18</sup>. In turn, the N-terminal corresponding to the first 18 residues and the linker region  
18  
19 (residues 164-170) are assumed to be unfolded and flexible in the Coral analysis.  
20  
21

22  
23 The CRYSON program <sup>52</sup> was used to calculate theoretical SAXS and SANS curves based on  
24  
25 structures (pdb codes) derived from the DAMMIN and CORAL analyses. This is especially useful  
26  
27 to compare CORAL structures to SANS data and thus verify their validity, while CORAL is  
28  
29 otherwise restricted to the analysis of SAXS data.

## RESULTS AND DISCUSSION

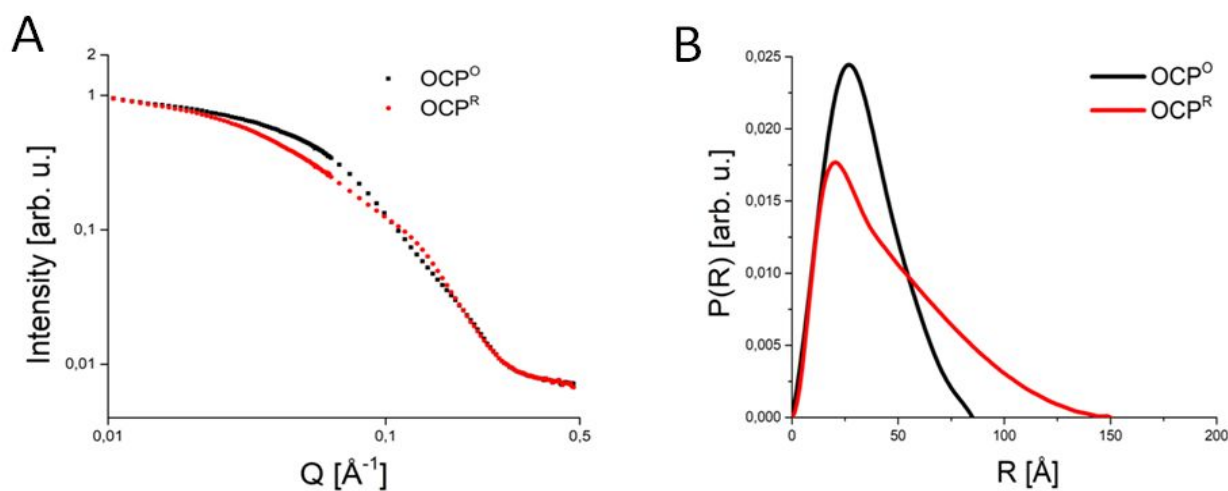

**Figure 2:** SANS experiments of OCP under blue light illumination. A: Illumination setup for OCP at the KWS-1 SANS instrument. B: An OCP sample after SANS experiment with illumination at KWS-1: While the upper non-illuminated part of the sample retains its orange color characteristic for OCP<sup>0</sup>, the lower illuminated part reveals a color change as expected for OCP<sup>R</sup> (illuminated region is indicated by the blue rectangle). Only the lower (illuminated) part of the sample cell is probed in the SANS experiment.

**SANS experiments:** SANS experiments of OCP with and without illumination were carried out at KWS-1. For these experiments the SANS instrument was interfaced with an illumination setup consisting of a laser emitting at 480 nm and a fiber optics to guide the excitation light to the sample (see Fig. 2A). The light intensity was about 5 mW/cm<sup>2</sup> on the surface of the cuvette. At this intensity a turnover of OCP<sup>0</sup> to the active state OCP<sup>R</sup> of more than 90% is achieved at 15°C, so that the illuminated part of the sample appeared clearly red, while the non-illuminated part of the sample, which was outside of the neutron beam, remained orange (see Fig. 2B). Consequently, SANS experiments for all samples were carried out at 15°C in order to ensure comparability of the

1  
2 data. The SANS curves of OCP<sup>O</sup> obtained with this setup in the dark (green circles) and of  
3  
4 illuminated OCP identified with OCP<sup>R</sup> (red squares) at a low protein concentration of about  
5  
6 1 mg/ml are shown in Fig. 3. The two curves exhibit a clear difference in the range of intermediate  
7  
8 Q-values. Upon illumination, the curve is shifted towards smaller Q-values indicating an elongation  
9  
10 of the OCP molecule in its active state. The SANS data of the OCP<sup>W288A</sup> mutant obtained for a  
11  
12 protein concentration of about 1 mg/ml are also shown in Fig. 3 (cyan triangles). A comparison  
13  
14 reveals that the SANS data of OCP<sup>W288A</sup> are very similar to those of OCP measured under  
15  
16 illumination. This finding is in qualitative agreement with the assumption that OCP<sup>W288A</sup> closely  
17  
18 mimics the structure of the active state OCP<sup>R</sup>. Although the data of OCP<sup>W288A</sup> are slightly noisier  
19  
20 than the other data sets, a small deviation from the OCP<sup>R</sup> data is visible in the Q-range between  
21  
22 0.07 and 0.10 Å<sup>-1</sup>. This deviation cannot be attributed to a possibly incomplete turnover of OCP  
23  
24 upon illumination, because this effect would lead to a shift of the curve attributed to OCP<sup>R</sup> towards  
25  
26 higher Q-values, i.e. the opposite of the observed deviation. The data shown in Fig. 3 appear to be  
27  
28 free of undesired effects from sample aggregation. This is important since aggregation is known to  
29  
30 severely affect spectroscopic properties of pigment-protein complexes<sup>53-55</sup>.

**Figure 3:** SANS data of OCP at a protein concentration of about 1 mg/ml obtained in the dark (green circles) and under constant illumination at 480 nm (red squares), respectively, measured at temperature of 15 °C using the instrument KWS-1. SANS data of OCP<sup>W288A</sup> measured under the same conditions are shown as cyan triangles. The black solid lines represent the fitting curves of the ellipsoid model (see Table 1).

**Figure 4:** A panel: SANS data of OCP at a protein concentration of about 65 mg/ml obtained in the dark (black dots) and under constant illumination at 480 nm (red dots), respectively, measured at temperature of 15 °C using the instrument KWS-1. The experimental error is in the order of the symbol size. B panel: Comparison of P(R) functions calculated from SANS data for OCP<sup>0</sup> (black line) OCP<sup>R</sup> (red line) samples.

1  
2 SANS data for a drastically higher protein concentration of about 65 mg/ml are shown in Fig. 4A  
3  
4 for OCP in the dark (black dots) and under constant illumination at 480 nm (red dots) at 15 °C.  
5  
6 These conditions are identical to those employed in neutron spectroscopy to study protein dynamics  
7  
8 in the accompanying paper and, thus, characterize the solution structure of the samples used in  
9  
10 these complementary experiments. The data shown in Fig. 4A are identical within experimental  
11  
12 error to those of the low concentration samples (see Fig. 3). This corroborates that the effect of  
13  
14 illumination on the solution structure of OCP remains virtually the same at higher concentration.  
15  
16 A very slight increase of SANS intensity towards the lowest Q-values indicates only a small  
17  
18 contribution from potential sample aggregation at this very high protein concentration. Overall, the  
19  
20 effect of light excitation on the SANS data has a similar qualitative effect as reported previously  
21  
22 by Gupta et al. <sup>8</sup>, while the effect appears to be more pronounced in Fig. 3 and especially the data  
23  
24 of highly concentrated OCP shown in Fig. 4A are characterized by an unparalleled signal-to-noise  
25  
26 ratio. This can be mainly attributed to the careful investigation of excitation conditions (see  
27  
28 Methods) leading to an almost complete turnover towards OCP<sup>R</sup>, but also to the high data quality  
29  
30 achieved on the KWS-1 SANS instrument.  
31  
32  
33  
34  
35  
36

37 Based on the SANS data shown in Fig. 4A, the solution structures of OCP in the dark and under  
38  
39 illumination can be characterized by the corresponding pair correlation functions P(R) as shown in  
40  
41 Fig. 4B. An inspection of these results reveals that OCP elongates towards longer radii upon  
42  
43 illumination, while the maximum of the P(R)-function tends towards a slightly smaller value. This  
44  
45 indicates that the molecule becomes longer and less compact on one hand, but also loses size in  
46  
47 the intermediate dimensions around the maximum of P(R). This is also reflected in the results of a  
48  
49 model dependent fit using the shape of an ellipsoid compiled in Table 1. OCP<sup>O</sup> is characterized by  
50  
51 radii of the ellipsoid of a=9.4 and b=29 Å as well as a radius c=50.8 Å. In contrast, both OCP<sup>R</sup> and  
52  
53 OCP<sup>W288A</sup> exhibit a considerably larger radius c of 85 and 92 Å, respectively, but a smaller  
54  
55  
56  
57  
58  
59  
60

1 dimension of the ellipsoidal radius b on the order of 19 Å. Although the dimensions of radius c  
 2 appear to be slightly different in OCP<sup>R</sup> and OCP<sup>W288A</sup> suggesting a possible structural difference,  
 3 we note that the values are similar within experimental error, see also data statistics and fit quality  
 4 in Fig. 3. Structure reconstitutions of OCP<sup>R</sup> and OCP<sup>W288A</sup>, respectively, are presented below.

**Figure 5:** Analysis of SANS data of OCP at a protein concentration of about 1 mg/ml measured in the dark at 15 °C (cyan dots): The fit (black line) corresponds to the reconstructed solution structure of OCP (depicted by grey spheres in the inset) obtained using the software package DAMMIF. The crystal structure of dimeric OCP<sup>0</sup> by Wilson<sup>18</sup> (PDB-code 3MG1) is shown in the insert for comparison.

**Solution structure of OCP<sup>0</sup>:** The solution structures of the OCP samples were generally obtained from the SANS data measured at the lowest protein concentration of about 1 mg/ml in order to reduce the influence of protein-protein interactions. This is because effects from protein-protein interactions may be expected at higher concentrations<sup>56, 57</sup>. SANS data of OCP measured in the dark at 15 °C using the instrument KWS-1 are shown as cyan circles in Fig. 5. The solution structure of the sample depicted by grey spheres in the inset of Fig. 5 is reconstituted from the SANS data using the DAMMIN software package (see Table 2 for full set of parameters). The latter structure yields the SANS curve shown as a black line in Fig. 5. The corresponding crystal structure of dimeric OCP is also shown in the inset of Fig. 5, A comparison reveals that the structure reconstituted from the SANS data widely resembles size and shape of an OCP<sup>0</sup> dimer suggesting

1  
2 that the OCP sample is preferentially dimeric. It has to be mentioned that previous studies reported  
3  
4 the presence of different OCP oligomers, but especially monomers and dimers, in solution samples  
5  
6<sup>58</sup>. Although this distribution is not visible here, our model has thus to be considered as a minimal  
7  
8 description of the SANS data.

50 **Solution structure of the mutant OCP<sup>W288A</sup>:** As already mentioned in the introduction, OCP<sup>W288A</sup>  
51 is often viewed as a structural analogue of the active state OCP<sup>R</sup><sup>59</sup>. The SANS data of the mutant  
52 OCP<sup>W288A</sup> are shown in Fig. 6 by purple circles (see also Fig. 3). For comparison, the fit function  
53  
54 determined for OCP<sup>O</sup> above is also shown as a grey line in Fig. 6, which clearly deviates from the  
55  
56  
57  
58  
59  
60

1 data. The fit obtained using DAMMIN (see Table 2 for full set of parameters) shows an excellent  
2 agreement with the data in Fig. 6 and corresponds to the reconstituted solution structure of the  
3 OCP<sup>W288A</sup> sample given by grey spheres in the inset of Fig. 6. In contrast to the rather compact  
4 form of OCP<sup>O</sup> (see Fig. 5), the reconstituted structure of OCP<sup>W288A</sup> appears elongated, but slightly  
5 narrower. This is the same effect as observed when applying the ellipsoidal model (see Table 1)  
6 and consistent with previous studies of OCP<sup>W288A</sup> <sup>59</sup>. The more detailed structural model shown in  
7 the inset of Fig. 6 is obtained using CORAL from SAXS data of OCP<sup>W288A</sup> and discussed in more  
8 detail below. A theoretical SANS curve can be derived from the CORAL structure using the  
9 CRYSON routine and yields a fit of the same quality as the black line in Fig. 6 (not shown).

24 **Solution structure of OCP<sup>R</sup> obtained by in-situ illumination:** In order to test the expected  
25 similarity between the solution structure of OCP<sup>W288A</sup> on one hand and that of the active state OCP<sup>R</sup>  
26 on the other, we also modeled the SANS data of OCP under illumination shown as green dots in  
27 Fig. 7. As outlined above, we achieved a conversion of OCP to OCP<sup>R</sup> of well above 90% by  
28 illumination with blue-light at 15°C (see also Fig. 1 for a picture of the converted sample) so that  
29 the sample under study widely reflects OCP<sup>R</sup>. The sample was the same as that used to produce the  
30 data of OCP in the dark shown in Fig. 5. For comparison, the fit function of dimeric OCP<sup>O</sup> is given  
31 as a grey line in Fig. 7 (this is the same fit function used for OCP in the dark in Fig. 5). It is apparent  
32 that the SANS curve calculated based on the ground state structure of OCP cannot describe the  
33 data collected under illumination. In contrast, the fit function obtained by DAMMIN (see Table 2  
34 for full set of parameters) under the same conditions as described above for OCP<sup>W288A</sup> shows a  
35 very good agreement with the experimental data of OCP<sup>R</sup> (see black line in Fig. 7). That is, the  
36 structural model derived for the mutant OCP<sup>W288A</sup> is also valid for the active state OCP<sup>R</sup> as achieved  
37 by in-situ illumination of an OCP sample. The observation of a generally elongated structure of the

**Table 2.** Fit parameters obtained from DAMMIN structure reconstructions of SANS data of OCP<sup>O</sup> and OCP<sup>W288A</sup>, respectively.

Fit parameters	OCP <sup>O</sup>	OCP <sup>W288A</sup>	OCP <sup>R</sup>
$R_g$ (Å)	26.6	40	37.4
$D_{max}$ (Å)	85	170	150
$Q_{min}$ (Å <sup>-1</sup> )	0.01	0.01	0.01
$Q_{max}$ (Å <sup>-1</sup> )	0.3	0.17	0.3
Chi <sup>2</sup>	0.01	1.703	0.06

**Solution structures at high protein concentration verified by SANS and SAXS:** As pointed out in the Introduction, the active state OCP<sup>R</sup> may not only be characterized by a specific structure, but also by a high degree of molecular flexibility referred to as a “molten globule state”. Protein dynamics/flexibility can be directly investigated by neutron spectroscopy as demonstrated for OCP in the accompanying paper <sup>60</sup>. As a general drawback, neutron spectroscopy requires a rather high protein concentration of > 50mg/ml in order to increase the contribution of protein scattering compared with that of the solvent. Such conditions may lead to formation of higher oligomers <sup>22</sup>, <sup>58</sup> or even significant non-systematic sample aggregation. In turn, the sample structure may be significantly affected so that the measured dynamics cannot be unambiguously related to the inferred structures of the ground and active states of OCP, respectively. Therefore, the solution structures of the OCP and OCP<sup>W288A</sup> samples employed for QENS were verified using SANS and SAXS, respectively. SANS data of OCP measured using the instrument KWS-1 at a protein concentration of about 65 mg/ml and at a temperature of 15 °C are shown as blue dots in Fig. 8. The data were fitted using the reconstituted structure of dimeric OCP<sup>O</sup> obtained at low

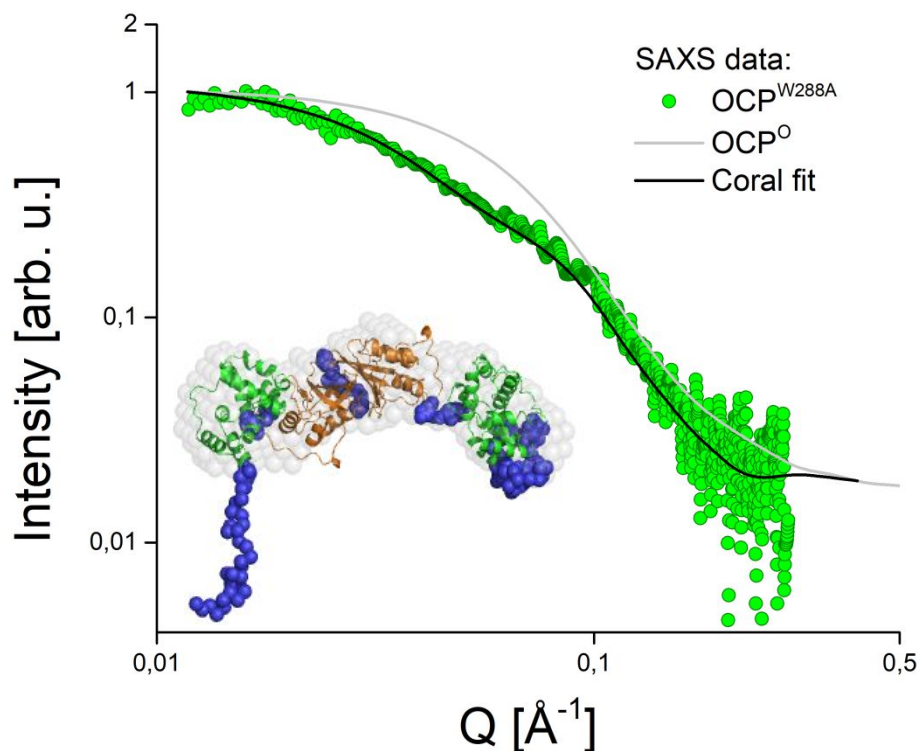

concentration above (see black line in Fig. 5), which results in the red line in Fig. 7. In addition, a power law representing a minor fraction of aggregates (blue line) has to be taken into account to describe the data. The full fit is shown as a black line in Fig. 8. Thus, it can be concluded that the OCP sample for QENS experiments is preferentially dimeric (grey spheres in Fig. 5) and only slightly affected by aggregation despite of the relatively high protein concentration.

**Figure 8:** Verification of the solution structure of the OCP sample at a protein concentration of about 65 mg/ml using SANS data measured at 15 °C (blue circles). The fit (black line) was obtained as the sum of the reconstructed solution structure of OCP (red line) using the software package DAMMIF (see Fig. 5) and a power law accounting for aggregation (blue line).

In a first attempt of QENS experiments on OCP, OCP<sup>W288A</sup> will be used as a structural analogue of the active state OCP<sup>R</sup>. SAXS data of OCP<sup>W288A</sup> measured at a protein concentration of about 65 mg/ml at 20 °C are shown as green points in Fig. 9. The SAXS data of OCP<sup>W288A</sup> were fitted using the same dimeric model as shown in Fig. 6 (see black line in Fig. 9) for the mutant sample at

1  
2 a protein concentration of 1 mg/ml exhibiting the expected elongated structure. This confirms that  
3  
4 the OCP<sup>W288A</sup> sample prepared for QENS is virtually free of aggregation and corresponds to the  
5  
6 active state structure OCP<sup>R</sup>, i.e. the samples can be used for neutron spectroscopy and the measured  
7  
8 molecular dynamics can be related to the above solution structures.  
9

38 **Figure 9:** Verification of the solution structure of OCP<sup>W288A</sup> at a protein concentration of about 65 mg/ml  
39 using SAXS data (green circles). The fit (black line) was obtained according to the CORAL structure of  
40 OCP<sup>R</sup> shown in Figs. 5 and 6. For comparison, the grey line shows the fit function of OCP<sup>O</sup> shown in Fig. 5.  
41  
42  
43  
44

45 **CORAL structural model of OCP<sup>R</sup>:** In order to achieve a better impression of the structural  
46 changes, we also modelled the SAXS data of OCP<sup>W288A</sup> using the CORAL routine. This package  
47 can be used for SAXS data only and allows defining flexible and rigid domains of the known crystal  
48 structure of dimeric OCP (Wilson et al. <sup>18</sup>, PDB-code 3MG1), respectively, whose arrangement is  
49 subsequently optimized to yield the best fit of the experimental data (see Methods). In our analysis,  
50 NTD (residues 19-163) and CTD of OCP (residues 171-311) were predefined as rigid bodies based  
51  
52  
53  
54  
55  
56  
57  
58  
59  
60

1 on the 3MG1 pdb code of the OCP<sup>O</sup> dimer<sup>18</sup>. In turn, the N-terminal corresponding to the first 18  
2 residues and the linker region (residues 164-170) are assumed to be unfolded and flexible in the  
3 Coral analysis. This approach is very similar to those used before for OCP<sup>8</sup> and OCP<sup>W288A 10</sup>.  
4  
5  
6  
7  
8  
9 Following Maksimov et al.<sup>59</sup>, however, the two OCP molecules of the dimer are associated via  
10 their CTDs (see orange structure in Fig.1). This assumption is based on the observation that  
11 separate CTDs form dimers in solution, while dimerization is not observed for NTDs. A similar

Since the crystal structure of OCP<sup>O</sup> suggests dimerization via NTDs in the inactive ground state of  
OCP, an association of OCP<sup>R</sup> dimers via their CTDs appears surprising at first glance. However,  
there are a number of arguments which support the structural organization of OCP<sup>R</sup> as shown in  
Fig. 9: i) a CORAL model of OCP<sup>R</sup> assuming association via NTDs (not shown) consistently  
exhibits the same basic features like domain separation and NTE unfolding as the model shown in  
Fig. 9, but has a higher Chi<sup>2</sup>-value and is thus less probable, ii) the interaction between OCP<sup>O</sup>  
monomers appears to be weak and relies on a few charged protein residues only, which are -  
according to X-ray crystal structure information<sup>62</sup> – present in dimer-forming representatives of the  
OCP1 clade, but absent in members of the OCP2 clade occurring only as a monomer<sup>62</sup>, and iii)  
thus, it is a speculative but reasonable argument to assume that the light-induced structural changes  
within the NTD affect the weak association of the monomeric subunits via their NTDs and lead to  
a rearrangement of the dimer association as well. The latter assumption is also consistent with  
rather long conversion times to OCP<sup>R</sup><sup>16</sup>, which should allow large scale structural rearrangements  
within OCP itself, but also within the OCP dimer.

1  
2 The CORAL fit is shown as a black line in Fig. 9 and provides an excellent agreement with the  
3  
4 SAXS data set. A comparison of the obtained structure (see inset of Fig. 9) with the reconstitution  
5  
6 obtained above by DAMMIN (see Fig. 6) also reveals a good agreement except for the highly  
7  
8 flexible NTE. This is not surprising as the reconstruction tool DAMMIN is intended for application  
9  
10 to compact molecular shapes. The optimized structure of OCP<sup>W288A</sup> reveals all expected features  
11  
12 of the active state OCP<sup>R</sup> <sup>8, 10</sup> like: i) separation of the two domains resulting in a generally elongated  
13  
14 structure, and ii) unfolding of the NTE thus becoming a highly flexible entity (see especially the  
15  
16 OCP monomer to the left in the inset of Fig. 9). The difference between the two OCP monomers  
17  
18 shown in Fig. 9 can be viewed as a measure for the flexibility of the OCP<sup>R</sup> structure allowed within  
19  
20 the experimental uncertainty of the SANS data.

## 28 **Conclusions**

29  
30  
31  
32  
33 As pointed out in the introduction, crystal structures of the active state OCP<sup>R</sup> are not yet available.  
34  
35 In this regard, small-angle scattering methods combined with simulation software like the  
36  
37 reconstruction tool DAMMIN and optimization routine CORAL for flexible structures,  
38  
39 respectively, are valuable experimental tools to determine low-resolution structures in aqueous  
40  
41 solution. In addition, SANS structures are obtained in solution and thus under widely identical  
42  
43 conditions used for spectroscopic experiments to investigate the function of OCP. In summary, we  
44  
45 confirm that the structure of the active state OCP<sup>R</sup> is characterized by the separation of the two  
46  
47 domains NTD and CTD resulting in an extended structure along with unfolding of the NTE. The  
48  
49 NTE appears to be highly flexible allowing various local conformations. Our results largely  
50  
51 corroborate those of <sup>8, 10</sup> for the cases of OCP<sup>R</sup> and OCP<sup>W288A</sup>, respectively. However, we can  
52  
53 directly compare the latter to the solution structure of OCP<sup>R</sup> induced by in-situ illumination thus  
54  
55  
56  
57  
58  
59  
60

1  
2 confirming that OCP<sup>W288A</sup> can be used as a structural analogue of the active state OCP<sup>R</sup>. We can  
3  
4 also confirm that the latter active state structures remain largely valid for samples at high protein  
5  
6 concentrations of >50 mg/ml as used for neutron spectroscopy experiments on protein dynamics in  
7  
8 the accompanying paper.
