Supporting Information

ABSTRACT: Understanding and controlling the crystallization of organic–inorganic perovskite materials is important for their function in optoelectronic applications. This control is particularly delicate in scalable single-step thermal annealing methods. In this work, the crystallization mechanisms of flash infrared-annealed perovskite films, grown on substrates with lithographically patterned Au nucleation seeds, are investigated. The patterning enables the *in situ* observation to study the crystallization kinetics and the precise control of the perovskite nucleation and domain growth, while retaining the characteristic polycrystalline micromorphology with larger crystallites at the boundaries of the crystal domains, as shown by electron backscattering diffraction. Time-resolved photoluminescence measurements reveal longer charge carrier lifetimes in regions with large crystallites on the domain boundaries, relative to the domain interior. By increasing the nucleation site density, the proportion of larger crystallites is increased. This study shows that the combination of rapid thermal annealing with nucleation control is a promising approach to improve perovskite crystallinity and thereby ultimately the performance of optoelectronic devices.

KEYWORDS: perovskite patterning, *in situ*, flash infrared annealing, crystallization, nucleation

1. INTRODUCTION

Perovskite solar cells (PSCs) have seen a rapid increase in power conversion efficiency (PCE) over the past decade of research to 25.5% now, approaching that of established technologies.^{1–4} Reaching ever closer to the theoretical Shockley–Queisser limit at PCEs of ~33%,^{5,6} increasing focus has shifted toward the long-term stability (i.e., device lifetime) of PSCs and possible strategies for upscaling from a lab- to industry-scale production.⁷ The commonly employed antisolvent method, where an antisolvent is dripped onto the liquid precursor, however, is challenging to scale-up at a potentially high economic and ecological cost.⁸

Drawing inspiration from the market-leading silicon-based photovoltaics (PVs), large single-crystal active layers are a proposed ideal.⁹ However, challenges remain related to the incorporation of perovskite single crystals into the overall device architecture and ensuring optimal contacts to the electron/hole selective layers to reach polycrystalline PCEs,¹⁰ and the fabrication of single-crystal perovskite devices is often still complex.^{11,12} Whereas high-end fabrication methods, for instance, metal–organic chemical vapor deposition or hybrid vapor phase epitaxy, bring other crystalline thin-film PV technologies close to PCEs of 30%,^{1,13,14} new strategies are required to push for such efficiencies in PSCs.

Therefore, in order to maintain the advantages of solution-based processing and controlling the film crystallinity, a major challenge is to fundamentally understand and control the crystallization processes when the perovskite active layer is formed from its precursors, most commonly from a solution or vapor.^{7,15–17} Although perovskites show a remarkable tolerance to defects,¹⁸ it has also been observed that the boundaries of individual crystallites (often referred to as *grains*) are frequently the origin of degradation processes.¹⁹ Strategies to mitigate performance losses include precursor additives to control morphology, passivation with polymeric nanolayers, and stoichiometric tuning of the perovskite, all of which come with increased complexity and drawbacks.^{20–24} A comprehensive understanding of perovskite film growth mechanisms is not only critical for the benefit of solar cell applications but also for other emerging perovskite-based light technologies such as light-emitting devices, detectors, lasers, and sensors, for

many of which patterning of the perovskite material has gained considerable attention.^{25–27}

In this work, we employ a model system that spatially predetermines nucleation sites for perovskite films annealed by the flash infrared annealing (FIRA) method.^{28,29} This approach is also suitable for other antisolvent-free thermal annealing methods compatible with large-scale device production (e.g., meniscus-assisted printing),³⁰ where the crystallization process is exclusively driven by thermal evaporation of the solvents.^{31,32} Methylammonium lead triiodide (MAPbI₃), one of the most studied perovskite compositions, was selected here to demonstrate the facile crystallization control. The FIRA method, yielding highly efficient MAPbI₃ PSCs, was used to anneal MAPbI₃ films on substrates with photolithographically patterned arrays of Au nucleation seeds.³³ The resulting morphologies are then characterized using electron backscattering diffraction (EBSD) and time-resolved photoluminescence (TRPL) mapping. Other perovskite compositions were then investigated in the same manner to further elucidate the crystallization dynamics.

To gain further insight into the morphology evolution of perovskite films, we combine the deterministic nucleation-site patterning with an *in situ* observation method by optical microscopy.³⁴ The patterned nucleation seeds enable us to

identify the location of nucleation a priori in order to investigate the nucleation and crystal growth dynamics of the perovskite films. We also show that the method of prepatterned nucleation sites can be generalized to other commonly used perovskite compositions.

2. RESULTS AND DISCUSSION

2.1. Prepatterned Perovskite Films Annealed by FIRA. FIRA is a rapid antisolvent-free annealing method that produces perovskite films with distinct polycrystalline morphologies that exhibit large polycrystalline domains. Each of these domains forms from a nucleation site, and they produce a weighted Voronoi tessellation according to the geometry of the nucleation sites.^{28,35} The weighting in the Voronoi tessellation results from a temporal variance of the spontaneous supersaturation-driven nucleation, where spontaneous nucleation can be both homogeneous nucleation from the precursor solution and heterogeneous nucleation caused by contaminants, the substrate surface, or the liquid–gas interface.³⁶ Each domain has a characteristic intrinsic morphology consisting of small individual crystallites in the center close to the nucleation site and larger crystallites close to the boundaries of the domains.³⁷ The diameters of the domains are typically in the 100–300 μm range.²⁸

Figure 2. Micromorphology of rapid thermally annealed MAPbI₃ crystal domains. (a) EBSD map indicating the crystallographic orientations in *z*-direction. (b) SEM image indicating the measured area within the pattern for EBSD mapping. (c) Kikuchi patterns identifying the two dominant crystallographic orientations. (d) Distribution of crystallographic orientations over the measured area. (e) XRD data for a prepatterned MAPbI₃ film on an ITO-coated glass substrate.

The domain nucleation sites can be spatially predetermined by patterning silicon and tin-doped indium oxide (ITO)-coated glass substrates with hexagonal arrays of Au seeds, as demonstrated by Geske et al.³³ They hypothesize a lowering interfacial energy at the Au surface caused by a catalytic effect of Au to give rise to the nucleation effect. The details of this nucleation effect are, however, currently unclear.

In the present study, the reported patterning method is combined with the FIRA deposition and annealing protocol for the manufacture of prepatterned MAPbI₃ and methylammonium lead tribromide (MAPbBr₃) films, as previously established by Sánchez et al.,²⁹ that has demonstrated competitive device performances. The prepatterned perovskite films of this study, therefore, resemble the nucleation and crystallization kinetics under deposition parameters relevant to the rapid thermally annealed high-performance PSCs.

Figure 1a–c and d–f show MAPbI₃ and MAPbBr₃ films annealed by FIRA, respectively, for various pitch sizes of predetermined nucleation sites (Au patches on Si substrate, as shown in the inset in Figure 1a). By varying the distance between the Au seeds, the density of the nucleation sites, and thus the shape and size of the domain, can be controlled. Si- and ITO-coated glass substrates were prepatterned to obtain compact perovskite films with hexagonal domains of tunable diameters in the 30–100 μm range. The geometric regularity of the domains within the patterns shows that predetermined nucleation has very little temporal variance, that is, all nuclei form almost simultaneously, producing an unweighted Voronoi tessellation, whenever sufficient precursor material is available for the domains to grow until they meet. At spacings larger than 100 μm, spontaneous nucleation was observed, forming perovskite domains between the Au-seeded domains. At patch distances of 30 μm and below, the diffusion of precursor

molecules toward the crystallisation front leads to depleted areas between the isolated domains, as shown in Figure 1a,d–f. Note, however, that despite the precursor depletion at a seed pitch of 30 μm, as in Figure 1a, some of the domains appear to have hexagonal shapes. This is due to a surface tension and convection effect in the precursor solution during thermal annealing, which is further discussed below.

The depletion results from the vicinity of the seeded nucleation sites, as a higher density of growing crystal domains compete for precursor molecules. As the annealing conditions with FIRA were kept identical, the different film morphologies solely depend on the pitch of the patterned hexagonal Au seed arrays. Because the nucleation and crystal growth locally remove solutes from the solution, a concentration gradient is created with a lower solute concentration at the crystal growth front than in the bulk solution. Precursor molecules, therefore, diffuse toward the growing domains, which can lead to depleted areas for sufficiently small pitch sizes or low annealing temperatures, where thermal solvent evaporation does not outpace solute diffusion (see schematic in Figure 1g). At higher temperatures, crystal growth parallel to the substrate outpaces solute diffusion because of fast solvent evaporation. At the same time, increasing the array pitch, that is, the distance between Au seeds, results in a lower density of patterned nucleation sites competing for solutes and thus no complete solute depletion between the domains. For MAPbBr₃, the depletion effect is more prominent than for MAPbI₃, leading to entirely isolated domains that consist of only a few individual single crystals, even at array pitch distances of 50 μm, resulting in isolated platelets and partially connected domains (Figure S1). The cubic crystal lattice of MAPbBr₃ probably enables the growth of oriented cuboid

Figure 3. Time-integrated PL and τ maps of prepatterned (a,b) and reference (c,d) rapid thermally annealed MAPbI₃ films. Normalized TRPL decays at two different locations (A: domain interior and B: near-domain boundary) indicated in the lifetime maps for both the prepatterned (e) and the reference area (f). The prepatterned domains exhibit a larger area fill fraction of near-boundary crystallites with a higher carrier lifetime as compared to crystallites on the domain interior. The TRPL decays correspond to the average signal of 100 pixels.

single crystals, with one facet aligned to the substrate surface.^{33,38}

A simplified classical nucleation and crystal growth model is described by the so-called LaMer curve,³⁹ relating crystallization mechanisms to the solution concentration, which has also been applied to illustrate crystallization kinetics in perovskite films.^{28,40} The LaMer curve shows the concentration as a function of time, increasing because of solvent evaporation until the supersaturation limit for nucleation is reached. Once solutes are removed from the solution because of crystallization, the concentration decreases as a result. The absence of spontaneously nucleated domains, according to the LaMer model, between the Au-seeded domains in all prepatterned films indicates that the solution film in the prepatterned regions never reaches the supersaturation threshold required for spontaneous nucleation, C_{sup} , as indicated in the modified LaMer curve in Figure 1h. Instead, nucleation at the Au seeds occurs at a lower concentration, C_{Au} . Although continued heating leads to sustained solvent evaporation, the simultaneous crystallization of the precursor molecules counteracts the increase in concentration, such that C_{sup} is never reached before Au-seeded domain formation and crystallization are complete. This is discussed in more depth below.

As standard scanning electron microscopy (SEM) imaging is limited in identifying the crystalline nature of the domains, EBSD mapping was used to compare the micromorphology of prepatterned MAPbI₃ domains with spontaneously nucleated films, by determining the spatial distribution of crystallites within the domains, their dimensions, and orientations (Figure 2a–d). Figure 2a shows the overlap of the image quality (brightness, IQ) with the inverse pole figure (color, IPF), representing the signal intensity and the crystal orientation obtained from fitting the Kikuchi lines (Figure 2c) to each pixel of the scanned area perpendicular to the substrate, respectively. Perpendicular to the substrate (z -axis), EBSD reveals domains preferentially oriented along the (112) and (100) orientations, as confirmed by the X-ray diffraction (XRD) data shown in Figure 2e. The XRD data are indicative of the characteristic preferential crystal orientations (112) and (100), showing peaks at 20° corresponding to the (112) and (200) reflections and at 40.5° corresponding to the (224) and (400) reflections that are also observed in nonpatterned

MAPbI₃ perovskite films³⁷ annealed by FIRA and in orientationally pure crystalline films grown in a thermal gradient parallel to the substrate.^{41,42} EBSD mapping allows to distinguish individual crystallites by determining their in- and out-of-plane crystal orientations, showing that crystallites close to the domain boundaries tend to be larger than those in the interior of the domains. This polycrystalline morphology of the domains with increasing crystallite sizes toward the domain boundaries, revealed by the EBSD measurements, indicates that a secondary heterogeneous nucleation process, originating from the crystal growth fronts at the substrate surface or the liquid–gas interface, gives rise to the characteristic crystal morphology of the domains. For completeness, the crystallographic orientations along x - and y -directions are shown in Figure S2.

If the crystallite size depended only on their absolute distance to a nucleation site, increasing the nucleation site density would yield smaller domains and thus a smaller average crystallite size. However, the opposite effect is observed, where the larger boundary crystallites appear merely closer to the nucleation sites, indicating that the characteristic polycrystalline morphology is independent of the final domain size. Therefore, by increasing the nucleation density, the crystallite size distribution of the entire film is biased toward larger crystallite sizes.

The photoluminescence (PL) lifetime in perovskite films depends on the size of crystallites within a polycrystalline assembly.⁴³ TRPL mapping was used to investigate whether the crystalline morphology within the domains correlates with the optoelectronic properties. In these experiments, the spatially resolved PL intensity and charge carrier lifetime (τ) within a domain of prepatterned perovskite films were compared to an unpatterned reference area without Au seeds (Figure 3). Both areas show a strong correlation of crystalline micromorphology with the PL intensity (Figure 3a,b) and τ -maps (Figure 3c,d), indicating that micromorphology determines the luminescence and charge carrier dynamics. In the interior of the domains (position A in the PL maps), where the EBSD measurements show small crystallites, the lifetime is approximately 2 times shorter than that in larger crystallites near the domain boundaries (position B in the PL maps). Representative PL transients of these regions are illustrated in Figure 3e,f for the prepatterned and reference areas,

Figure 4. *In situ* observation of nucleation and crystallization of MAPbI₃ films on an Au-patterned Si substrate heated to a constant temperature of 110 °C. (a–e) Drop-cast; (f–j) spin-coated for 10 s at 4000 rpm (as for FIRA); and subsequently annealed at 110 °C during *in situ* observation.

respectively. Both the patterned and reference areas exhibit very similar decays in each region of ~ 5 ns in the interior (position A) of a prepatterned domain (6 ns for the reference) and ~ 11 ns near the boundaries (position B, 12 ns for the reference). Hence, we conclude that the characteristic micromorphology is preserved in Au-seeded prepatterned domains, and there is no evident modification of the PL characteristics by increasing the nucleation site density as compared to the reference area. By retaining this distribution of crystallite sizes within each domain, increasing the nucleation site density by patterning increases the proportion of large near-boundary crystallites that contribute to the overall longer PL lifetime of the entire perovskite film.

At the same time, seeding also has an effect on the morphology of the centers of the domains, that is, close to the nucleation site (Figure S3). The TRPL signal from the domain centers includes, however, a nonquantifiable contribution from the Au seed, making a TRPL comparison of the domain centers difficult. Unfortunately, because of the difference in roughness of the film between the center and the rest of the domain, EBSD mapping also was not able to resolve the crystallite dimensions at the domain centers. Figures S9 and S10 show exemplary atomic force microscopy (AFM) and cross-sectional SEM images, respectively. Note, however, that the topography and thickness of the films vary significantly with all the experimental parameters, such as Au array pitch, perovskite composition, annealing time, annealing temperature, and annealing method.

Note that the presence of Au seeds after crystallization could make this architecture impractical for use in solar cell devices because of the introduction of trap states and recombination sites as well as degradation processes because of Au migration.^{44,45} The deterministic nucleation effect of other metals (e.g., Pt and Cu) was also tested, but their effect was not as consistent as that of Au, whereas a nonmetallic material such as SiO₂ did not show a nucleating effect at all (Figure S4). A material that is chemically and optoelectronically inert after crystallization but provides a similar nucleation catalysis effect would be an interesting candidate material for future integration into devices.

2.2. In Situ Observation of Nucleation and Crystallization. To further study the dynamic formation kinetics of the domain morphologies on patterned and unpatterned substrates, we observed the nucleation and crystallization processes *in situ* under an optical microscope³⁴ using a heating stage to approximate the thermally induced solvent evaporation that drives the film crystallization in the FIRA experiments. Although FIRA is able to reach much higher

peak temperatures and, therefore, shorter annealing times, we show that the hot-plate annealing achieves the same characteristic film morphology. Figure 4a–e shows a sequence of snapshots corresponding to the different stages of nucleation and growth of MAPbI₃ perovskite domains. The substrate was heated to a constant temperature under the optical microscope followed by drop-casting 2 μ L of a precursor solution onto the substrate. In each experiment, visible nucleation occurred simultaneously at all seed patches (within 0.14 s). The growth rate, as defined by the area increase of the domains, was uniform, leading to regular hexagonal arrays of perovskite domains. Figure 4f–j shows a similar *in situ* experiment, in which the precursor solution was spin-cast onto the substrate, similar to the FIRA fabrication protocol. In these spin-coated films, a polycrystalline micromorphology similar to that in FIRA films was obtained (SEM image in Figure S5). The thinner spin-cast solution film leads to an initially growing domain that reaches the liquid–air interface, inducing a secondary heterogeneous nucleation on the surface of the solution film, such that the domain grows in an alternating cascade of nucleation- and diffusion-driven growth.

The observations in the *in situ* experiments confirm the regularity of the domain patterns observed in the FIRA samples (Figure 1a–f). The nucleation at the Au seeds was simultaneous, and the crystallization growth rate from each Au patch (Figure 1h) was uniform, which leads to nearly perfect honeycomb patterns, seeded by the hexagonal Au lattice. In this seeded nucleation process, the saturation threshold for nucleation is sufficiently lowered, such that no domains originating from spontaneous nucleation were observed in the area occupied by the Au seed pattern.

Compared to spontaneously nucleated FIRA domains, the precursor solution adjacent to the nucleated crystal growth front is, therefore, not close to the supersaturation limit, C_{sup} (Figure 1h), confirming the interpretation of the FIRA experiments (Figure 1a–f). Hence, secondary heterogeneous nucleation on the surface of the growing crystals is less frequent, resulting in fewer interruptions of growth of individual crystallites. This yields larger crystallites at the domain centers, relative to the domain interior, as shown in Figure S3.

In the case of spontaneous nucleation, the crystallization is overall faster because the solution is close to C_{sup} in the entire film, hence, also adjacent to a growing crystal domain. This, on the one hand, leads to rapid crystal nucleation and growth, outpacing solute diffusion to the crystallites. Although providing good substrate coverage, this, on the other hand,

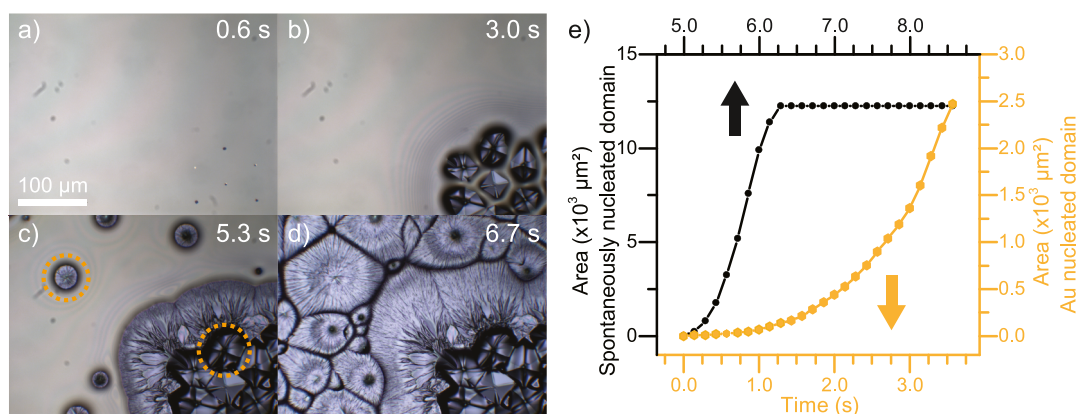

Figure 5. (a–d) MAPbI₃ crystallizing on a patterned Si substrate heated to 110 °C from a drop-cast precursor solution. The images view a corner of a patterned array and a substrate region without nucleation seeds. (e) Measured area of an Au seed-nucleated and a spontaneously nucleated domain with respect to the first frame in which they were visible [indicated by dotted circles in (c)].

Figure 6. (a–e) Triple cation perovskite, Cs_{0.05}(MA_{0.17}FA_{0.83})_{0.95}Pb(I_{0.83}Br_{0.17})₃, nucleating and crystallizing on an Au-patterned Si substrate from a drop-cast precursor solution on a hot plate set to a constant temperature of 110 °C. results in small individual crystallites that form in a series of interrupted nucleation and growth processes.

The interplay of solute diffusion and crystal growth rate also affects the substrate coverage in the Au-nucleated case (see Figure 1g). Lowering the saturation threshold of nucleation reduces the initial rate of crystal growth, and thus the diffusion of solutes is relatively faster, leading to larger crystallites but also a higher degree of material accumulation close to the nucleation site (i.e., locally thicker perovskite domains). Figure 5a–d shows a direct comparison of Au-seeded and spontaneous nucleation and subsequent diffusion-driven crystal growth of the domains in the same film. The time offset between the nucleation types correlates to the offset in supersaturation threshold values, C_{sup} and C_{Au} , as the solvent evaporates over time (Figure 1h). The images also show that the absence of spontaneous nucleation in the prepatterned areas, as discussed above, does not only arise from precursor depletion near the growing seeded crystals but also from the mentioned time offset because of different critical concentrations for the respective nucleation types. In the region beyond the Au-seeded pattern, spontaneous nucleation only occurs once the solution reaches C_{sup} , when the Au-seeded domains have already reached their maximum extent.

The difference in the crystal growth rate is shown in Figure 5e. Both for seeded and spontaneous nucleation, the final size of the domains is determined by the adjacently grown domains, that is, by the Voronoi tessellation of all nucleation sites. Spontaneous nucleation occurs for a more supersaturated

solution compared to seeded nucleation, and their rapid growth yields a different micromorphology.

The Au-seeded nucleation leads to diffusion-driven domain growth, whereas the spontaneously nucleated domain growth is characterized by a more rapid interplay between the diffusion-driven crystal growth and heterogeneous secondary nucleation of the highly supersaturated precursor solution near the surface of the crystal growth front. This growth mechanism leads to a starlike polycrystalline micromorphology similar to the morphology in MAPbI₃ perovskite films annealed by FIRA.^{28,37}

Seeding the nucleation of perovskite domains at low solution concentrations during solvent evaporation, thus, enables an improved control over the polycrystalline morphology in single-step rapid thermally annealed perovskite films. The effect of lowering the saturation threshold can, however, lead to disconnected domains because of material depletion between the growing domains, which is governed by an interplay of the crystal growth rate relative to the diffusion of the solutes and the distance between nucleation seeds. Well-defined disconnected perovskite domains may on the one hand be useful for some applications,⁴⁶ particularly in the case of cubic MAPbBr₃ that forms faceted isolated domains (Figure 1d–f). If, on the other hand, a uniform substrate coverage is desired, the nucleation site density and the annealing temperature have to be appropriately adjusted.

Importantly, Au-seeded patterning also works for a range of perovskite compositions such as the high band gap MAPbBr₃

(Figure 1d–f), the widely used triple cation $\text{Cs}_{0.05}(\text{MA}_{0.17}\text{FA}_{0.83})_{0.95}\text{Pb}(\text{I}_{0.83}\text{Br}_{0.17})_3$ (Figure 6a–e), and MA-free $\text{Cs}_{0.15}\text{FA}_{0.85}\text{PbI}_3$ (Figure S6).

In particular, the triple cation and dimethylformamide (DMF)-based MAPbI_3 offer further insight into the morphology formation in the single-step rapid thermally annealed perovskite films. At low growth speeds parallel to the substrate, pattern formation is aided by surface tension and convection effect, also observed in domain formation in the meniscus coating methods of perovskites.⁴⁷ The thin-film interference visible in the optical microscopy images in Figures 4 and 6 between the growing domains shows that the thickness of the solution film varies between the growing domains. This effect is strongest in the pure DMF-based MAPbI_3 depicted in Figure 6f–j, where dewetting of the solution film produces secondary and tertiary lattices of small domains. This ripple effect is due to a complex interplay of solution flow, solute diffusion, the solvent evaporation, and the crystal growth.^{48,49}

This effect depends strongly on the crystal growth kinetics and, thus, on both the perovskite composition and the solvent mixture. The pure DMF-based MAPbI_3 precursor solution lacks the crystallization retardation afforded by dimethylsulfoxide (DMSO), and the material accumulates more strongly close to the nucleation sites.

In the meniscus-assisted solution printing of perovskites, He et al. found an initially high crystal growth rate after nucleation, causing the domains to grow quadratically with time (corresponding to linear radial growth), and a second slower phase with a linear area growth caused by an overlap of the solute diffusion areas of several growing crystals.³⁰ Figure 5e shows an initial high crystal growth rate after nucleation in the *in situ* observation because of continued solvent evaporation. The growth rate reaches an inflection point when the diffusion areas of adjacently growing domains overlap, slowing down the crystal growth until the domains meet, forming their mutual boundaries. The change in growth rate corresponds to the observation of varying crystallite sizes within the domains, regardless of the domain size. Thus, the crystallite size within the micromorphology of the domains is determined by the crystal growth rate rather than the absolute distance to the nucleation site.

DMSO plays an important role in affecting the crystal growth rate. It strongly coordinates with PbI_6 molecules, forming a metastable intermediate phase in the crystallization process of MAPbI_3 , thus retarding the crystallization process.^{50–52} To understand its effect in the crystallization process, we repeated the *in situ* experiment with a precursor solution of MAPbI_3 in pure DMF. Figure 6b shows that, without the DMSO-mediated metastable phase, crystal growth parallel to the substrate is slowed down, suggesting that the intermediate phase is critical in achieving uniform compact films.

Moreover, at equal temperatures, the $\text{Cs}_{0.05}(\text{MA}_{0.17}\text{FA}_{0.83})_{0.95}\text{Pb}(\text{I}_{0.83}\text{Br}_{0.17})_3$ composition achieves more uniform substrate coverage compared to MAPbI_3 (see Figure 6a), suggesting that the high efficiency and stability of this perovskite composition do not only arise from its chemical composition but also that the heterogeneity in its components prevents a highly ordered faceted crystal growth immediately after nucleation.

Spatial heterogeneity in triple-cation perovskite films observed by Bercegol et al. suggests that Cs doping may facilitate favorable morphology evolution during crystallization

rather than optoelectronic effects because of its presence in the crystallized perovskite film.^{53,54} Figure S7 shows that the XRD measurement of a triple cation perovskite film annealed with FIRA is in good agreement with a reference film prepared with the antisolvent method. This is in contrast to a comparable MAPbI_3 study, which exhibits characteristic preferential crystal orientations after rapid thermal annealing (e.g., FIRA) but not when using the antisolvent method (Figure 2e).

In contrast, the highly symmetric cubic crystal lattice of MAPbBr_3 ³⁸ yields isolated highly faceted domains that appear to consist of only a few individual single crystals (see Figure 1d–f). Hence, although the consistent MAPbBr_3 pattern morphology shows that the saturation threshold for nucleation at the Au seeds is lowered similar to that of MAPbI_3 , the growth rate has to be significantly higher to achieve completely isolated platelets under the same experimental conditions that yield a complete substrate coverage by a MAPbI_3 film.

3. CONCLUSIONS

Using prepatterned substrates, the nucleation of domains was controlled with Au seeds in perovskite films annealed by FIRA. The seeding lowers the nucleation threshold, enabling an otherwise inaccessible regime in the kinetic space of nucleation and crystal growth. The modified nucleation site density and lowering of the nucleation threshold led to morphological differences that affect the micromorphology of the polycrystalline perovskite films and their optoelectronic properties. It was shown that the crystallite size in the domains correlates with the crystal growth rate and solute concentration at the crystal growth front of growing domains. This result is important as it allows to engineer the crystallite size in nucleated perovskite films, allowing a systematic study of the electronic effects of grain boundaries, which in the long run will enable to improve the performance and lifetime of devices.

Although Au seeds are reliable nucleation catalysts and are easily patterned onto substrates, they have the evident caveats in an optoelectronic device, introducing trap states and recombination sites and contributing to faster degradation mechanisms. In the case where geometric patterning is not desired but seeding-assisted morphology control of compact films is the objective, other seeding particles as additives such as quantum dots are beginning to be explored^{55,56} and should be of interest, especially in fabrication upscaling with single-step thermal annealing methods.

The spatial predetermination of the nucleation sites enables a detailed local study of the nucleation and crystal growth processes, as demonstrated in the *in situ* experiments. Knowing the location of the nucleation site and the direction and scope of crystal growth a priori enables the locally targeted study of the evolution from the precursor solution to perovskite crystal beyond the visual observation with the optical microscope.

Beyond PSCs, the deterministic patterning of isolated perovskite domains can be of interest for other applications of perovskite materials such as sensing, light emission (e.g., LEDs and lasers), and light detection. Further optimizing the seeding and annealing parameters with a device application in mind, obtaining large-scale perovskite arrays with near-single crystal morphologies, could be possible, similar to recent developments but compatible with the FIRA method.¹¹ This approach should be compatible with the thin-film transfer methods such as template stripping, for example, for applications requiring substrates that are incompatible with the growth of high-quality perovskite films.⁵⁷

4. EXPERIMENTAL SECTION

4.1. Substrate Patterning. A photoresist layer (ECI 3007, MicroChemicals) was spin-coated (Süss ACS200 Gen3) onto silicon- or ITO sputter-coated (500 nm, Pfeiffer SPIDER 600) glass wafers. Hexagonal arrays of discs with 3 μm diameter and of varying pitches were exposed by a laser writer (405 nm, Heidelberg MLA150) and developed (AZ 726 MIF, MicroChemicals). The wafers were then coated with a 1 nm Cr and a 15 nm Au layer by thermal evaporation (Minilab-80, Moorfield Nanotechnology), followed by a standard lift-off step (Remover 116S, Microposit), rinsing in IPA and H_2O , and a final blow dry with N_2 . The wafers were then diced into $12 \times 12 \text{ mm}^2$ samples using a diamond scribe.

4.2. Perovskite Synthesis. The lead iodide (PbI_2) and lead bromide (PbBr_2) precursors were purchased from TCI; the organic salts methylammonium iodide (MAI), methylammonium bromide (MABr), formamidinium iodide (FAI), and formamidinium bromide (FABr) from Greatcell Solar Materials; and cesium iodide (CsI), anhydrous DMF, and anhydrous DMSO from Sigma-Aldrich.

The methylammonium lead tri-iodide (MAPbI_3) and methylammonium lead tribromide (MAPbBr_3) precursor solutions were prepared by mixing a 1:1 ratio of MAI and PbI_2 and MABr and PbBr_2 , respectively, in a 3:1 v/v DMF/DMSO solvent mixture or in pure DMF to obtain a concentration of 1.2 M. The triple cation ($\text{Cs}_{0.05}(\text{MA}_{0.17}\text{FA}_{0.83})_{0.95}\text{Pb}(\text{I}_{0.83}\text{Br}_{0.17})_3$) precursor solution was obtained from a 83:17 v/v ratio of 1.24 M formamidinium lead tri-iodide (FAPbI_3) and MAPbBr_3 solutions, with an overstoichiometric ratio of 1:1.09 of both MABr/ PbBr_2 and FAI/ PbI_2 , prepared in 4:1 v/v DMF/DMSO. For the $\text{Cs}_{0.15}\text{FA}_{0.85}\text{PbI}_3$ perovskite, a 1.24 M 1:1.09 overstoichiometric FAPbI_3 solution was mixed with CsI in 4:1 v/v DMF/DMSO. The precursor solution preparation was carried out in a glovebox under a N_2 atmosphere.

The samples, using the FIRA method, were prepared by spin-coating the precursor solution in a single step at 4000 rpm for 10 s onto patterned Si or ITO-coated glass substrates (after 5 min O_2 plasma etching), then irradiated for 1.4 s in the FIRA chamber, and kept inside the chamber for an additional 20 s. The entire process was carried out in a glovebox under a N_2 atmosphere.

4.3. Microscopy and Structural Characterization. For *in situ* microscopy observations, the patterned silicon substrates were initially exposed to a 5 min O_2 plasma step and then kept at a constant elevated temperature on a Linkam HFS350X temperature-controlled stage installed under a ZEISS Axio Scope.A1 optical microscope equipped with a Point Grey Grasshopper3 camera using a 20 \times objective. Unless otherwise indicated, 2 μL of the respective precursor solution was drop-cast onto the heated substrate. The *in situ* observations were limited to patterned Si substrates, as the Au patches on ITO-coated glass substrates heat more strongly relative to the substrate than on Si, causing dewetting from these patches. In this case, perovskite nucleation occurs at the boundaries of the dewetted areas (Figure S8).

XRD measurements on the films were performed using a Rigaku Ultima-IV diffractometer using $\text{Cu K}\alpha$ radiation.

SEM images were obtained with a Tescan Mira3 LM FE SEM system, with a field emission source operated at an acceleration voltage of 5 kV using an Everhart-Thornley-type secondary electron detector.

For EBSD measurements, a direct-electron detector was used. A detailed description of the setup, data collection and procedure for fitting the Hough's space is reported in Muscarella et al.³⁷ 7 kV, 100 pA, 50 ms, 12.4 mm, 500 nm were used as voltage, current, exposure time, working distance and step size of the measurement, respectively. These scanning parameters correspond to a 5 nA ms electron dose per pixel. The collected Kikuchi patterns were indexed using the space group 14/*mcm* (tetragonal symmetry).

The TRPL mapping system is based on PicoQuant systems composed by a FluoTime 300 unit and a microscope system (MicroTime 100). For excitation, a 639 nm laser with ~ 100 ps pulse width with a frequency of 3 MHz has been used. The beam diameter was roughly 130 μm (13.5% metric), as measured with a NanoScan2

beam profiler. The excitation photon density was $\sim 2 \times 10^{12}$ photons/ cm^2 /pulse. To collect the emitted light, an Olympus long-range 20 \times objective (LCPLN20XIR) with a numerical aperture of 0.45 was used. The emitted light is guided to a detection fiber of 50 μm acting as a pinhole, which is coupled to the FluoTime unit including the input optics, to focus the light into the monochromator and the photomultiplier detector (PMA 192). A Time-Harp 260 Nano TCSPC card in long-range mode has been used for photon counting. A wide-range scanner stage from Physik Instrumente is used (M687.7) for mapping. The dwell time was set to 5 ms/decay with a step size of $\sim 0.5 \mu\text{m}$ /pixel. The system has a global illumination local detection configuration (wide-field) with an optical resolution of $\sim 2 \mu\text{m}$. A single exponential equation has been used to fit the decay at each pixel. The samples used for TRPL correspond to a layer structure glass/ITO/local Au seeds/ MAPbI_3 .
